THE

FARMERS' REGISTER:

A MONTHLY PUBLICATION,

DEVOTED TO THE

IMPROVEMENT OF THE PRACTICE,

AND

SUPPORT OF THE INTERESTS

OF

AGRICULTURE.

And he gave it for his opinion, "that whoever could make two ears of corn, or two blades of grass, to grow upon a spot of ground where only one grew before, would deserve better of mankind, and do more essential service to his country, than the whole race of politicians put together." *Swift.*

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

VOL. X.—1842.

TABLE OF CONTENTS OF VOL. X.

A

Age of cattle, shown by their teeth 29
Agricultural Society of South Carolina, extracts from an address to 246; of Prince George, and of King William, formed on the working plan 237; of Cayuga, address to 283; of Mason, Cabell and Kanawha, addresses to 91, 116—and premiums of 119; of Albemarle, address to 505; of Essex, address to 200; of United States, constitution of 19; remarks on 20, and reply 65
Agricultural survey of South Carolina, recommended by the State Agricultural Society 453
Agriculture, essay on the system best adapted to Kentucky 70
Agriculture, the Board of, its designed action 1; law concerning 138
Agriculture, Board of, debate in Virginia legislature concerning 213; remarks thereupon 217; reports to 241, 257, 274, 298, 335, 383, 512
Agriculture, of lower Virginia, defects of 264
Agriculture versus commerce 30
Agriculture of Pennsylvania 273
Alkalies in soils, importance of 5
"Amende honorable" 490, 499
Aqueduct, Croton, account of 394, 474
Aqueducts, ancient and modern 474
Artesian well of Grenoble 240
Ashes as manure 146
Asparagus, culture of in Spain 239

B

Banking of New England
Banks of Virginia, their condition, fraudulent procedure, and prospects 179; exposure of their false pretences of having resumed specie payments 63, 442
Bearing rein, objections to 333
Black, the worst color for wood in open air 110
Blossoming of fruit trees a second time 444
Blue grass, Kentucky, (green-sward) 56
Bone earth, mineral, 323
Bones, quantity shipped to Europe 415; imported into Hull 452
Brandon farming, account of 274
Broom corn, culture and value of 22
Butter, directions for making 28, 479, 493

C

Camels, use of, recommended for the western prairies 478
Canada thistle 352
Candles, dipped, the making of 55
Cane, history of 288
Canker worm 324, 482
Carrots for horses 414
Casks for preserving grain 288
Castor-oil, fatal effects of on a horse 496
Caterpillars on elms 349
Cattle, English, remarks on, and comparison of with American 79—newly brought to the south, how to be treated 108—driving of when restive 70—murrain of 78
Chalk hills of South Carolina, (improperly so called,) 486
Charcoal as manure 253, 430
Cheat, spelt and darnel, papers on 6, 7, 8
Chickens, gapes of 17
Cider, the making of 53
Climate of United States, advantages of, over that of England 115
Clover and timothy together 103—top-dressing of 130—gayting 158—husbandry, introduction and progress of 260—Buffalo 403—hay, a good mode of curing 414—Bokhara, 458, 500—soiling 500—grazed or not, comparison of in improving land 481
Coal beds of Appomattox, notice of 449
Cockroaches 38
Corn, Indian, on the question of topping and stripping 14—havesting the crop 15—comparative weight of grain and cob 21—for fodder 113—cultivation of 142, 213, 237, 251—grown for fodder 310—novel mode of cultivation 331—sown broad-cast 206, 444, 480, 497; protection of against crows 147
Corn stalks, crop of 2
Cotton seed, feeding on 256
Cotton, handling 353—benefit of heating 239
Cucumber bug 267
Curculio, fruit 207—habits of and means for destruction of 114
Cut-worm 99

D

Darnel or spelt 6, 7, 8
Degeneracy, physical, cause of 219
Diseases produced by local causes, queries on 69
Dismal Swamp, geological character of 353
Dogs, sheep-killing 109
Draining, covered, a cheap mode 494
Draining, the Deanston system, remarks on 318; mode and benefits of 463

E

Editorial articles and remarks on the Board of Agriculture and its designed action 1; on skippers in bacon 6; Cheat controversy 6; on Fourth Report of the Agricultural Survey of Massachusetts 12; on the humbugs of hog breeders 17; Agricultural Society of United States 20, 66; on the guano 56; on queries as to diseases from local causes 68; on the noting and reporting experiments and observations of useful facts 87; on the humbugs of Berkshire hogs, &c. 88; farming of J. H. Turner 96; on reports of farmers' conversations 123; on manuring grass 125; magnesian lime 134; gypseous earth and green-sand of James River 135; Apricot tree planted in marl 135; poudrette 135; inquiry as to failures of lime to act 154; the banks and the Farmers' Register; retirement of the editor announced 155; on rotations of crops 178; on northern opinions on lime 178; on the condition of the banks of Virginia, their fraudulent procedure, and their prospects 179; on weevil 208; on speeches and statements made in the House of Delegates on the Board of Agriculture 217; on personal controversy on agricultural articles 236; on the formation of the Prince George and King William Agricultural Societies 237; wire-grass kept down by top-dressing with leaves 253; notes to Mr. Turner's remarks on lime as manure 293; on his objections to the doctrine of rotation 301, 361, on changes of seeds, and Prof. Bronn's theory 309; on marling in South Carolina 367; on the manner of the rotation controversy 399; on the false pretences of the banks of having resumed specie payments 442; estimate of the value of marling in King William county 489; on the fence law of Pennsylania compared to that of Virginia 501; on transferring the conducting of Farmers' Register to T. S. Pleasants 504; notices to readers and subscribers 504; on proceedings of Agricultural Society of Prince George 524

'Essay on Calcareous Manures,' the publication of a new edition announced, as part of this volume of the Farmers' Register 368 [The entire work to form the 12th number of this volume, commencing after p. 524, and has its separate table of contents.]
Experiments, agricultural, need of 269

F

Farmers' Clubs, English, proceedings of 124, 322
Farmers' conversations, scraps of 84
Farmers' Register, transfer of editorship announced 504
Farming, at Westover 169: in Massachusetts, particular results of 111
Farming of the Rev. Jesse H Turner, requested to be reported, 96; account of, No. I., 127; No. II, 150; No. III. 154; IV. 230; No. V. (remarks on lime) 290; editorial remarks in reply to 290
Farming of Wm. Weaver described 411
Farms, model, in France 322
Fence law in Pennsylvania, the enormous and useless cost of 502; of Virginia, its disadvantage and cost to agricultural interests 513
Fires, frequent causes of 255
Fisheries, shad 218
Food and manure, facts on 126
Forage crops of France 372
Forest trees 405
Fowls, domestic, winter management of 415
Fruit garden 311
Fruit trees, to force their bearing 148; on pruning 222

G

Gapes in chickens 157
Gelding animals 252
Genesee valley, account of its agriculture 403, 410
Geometers (insects) 324
Glowworm, a splendid kind 414
Grafting, new method of 501
Grain crops (or cereal plants) of France 391
Grain, on storing 462; practical hints 147
Grapes, exhibition of 4—Isabella and Catawba, comparison of 266
Grass culture, essay on 120—artificial, essay on 364—on laying land in 438—artificial, cultivation of 453
Grasses and grass culture of France 10, 208—in Franklin county, Massachusetts 13
Green crops ploughed under 188
Green-sand earth (or gypseous earth) of James River, experiments with 86; good effects of recently observed 252—of New Jersey, account of the deposites and the use of in improving lands and crops 418
Grub-worm, salt to destroy 413
Guano, account and uses of 50, 104
Gypsum as manure, report on 270; effects of 199; experiments with 86

H

Harvest, wheat 304
Hay, cutting and product of 191
Hemp, on the fitness of the North Carolina swamp lands for its culture 512; inquiry concerning 492
Hens, to make lay perpetually 146
Hessian fly 350
Hill-side ditches, to prevent washing 390
Hints and observations on sundry heads 66
Hog-feeding, facts of 108
Hogs, Berkshire 76; comments on several articles respecting 67; comparative merits of the Berkshire and Woburn breeds 15; humbuggery in regard to sales 17; white 27; wild in Louisiana 371; Berkshire 29; management and breeds of in Middlesex, Massachusetts, 42; worms in kidneys of 50; experiment in fattening 12
Horse, geological history of 431; shoeing of 479; training of 341
Husbandry of Scotland, improvements of 227

I

Imports and exports of United States, values of from 1821 to 1841, 367, 368
Insects, destructive, account of 267
Iron hoops for cotton bales 256
Irrigation 193
Islands, floating, described 481, 498

L

Lambs, to protect from foxes 413
Lard oil, and stearine 173
Lands, choice of indicated by the growth 233; choice of 321
Lice on chickens 476; on cattle, &c. 100
Lime, opinions of northern farmers concerning 178; as manure, and calcareous formations of limestone region 38; use of in Scotland 223; (or carbonate of lime) as manure, remarks on 298; benefits of 304; in lower Virginia 260; magnesian, opposite opinions concerning 131, 132, remarks on 134

M

Mange in dogs, cure of 12
Mangel wurtzel and Swedish turnips, comparative feeding properties of 50
Manure, liquid 87, 266; manufactured in England 498; on the making, preserving and applying of 136, 477; new artificial, 305, 306; materials for, the great loss of in Massachusetts 497; on making &c., (reply to strictures) 184; urine 219; essay on making, preserving and applying 34; preservation of 49; salt-marsh grass and mud 81; discussion on 110; mineral 457; stable, cow and hog yards 23; human excrement 23; compost of swamp mud, &c. 25; saltpetre 26; experiments with 462; rejoinder to remarks on general management of 235; animal, on the chemical changes produced in different modes of preparing 339; remarks and inquiries on 100; mixed earth and creek mud 188; yard and stable dung and tanner's bark 188; green crops 188; ashes 146; artificial 460; different kinds of reported upon 2
Manuring by non-grazing 257; by top-dressing 262
Marl (so called) of New Jersey, account of its use and effects 418, 488
Marl beds of New Jersey 445
Marling executed, extent of in King William county 488; estimate of the profit and value thence accrued 489; in South Carolina 190, 519; progress of in South Carolina 266; beginning and progress of 258
Marls and soft limestone of South Carolina 486
Mercantile life, risks of 376
Molasses made from corn stalks 498
Mosquitoes 19
Murrain in cattle 78

O

Oat hay 416
Observations and rough experiments—gypsum, green-sand earth, old seed wheat, top-dressing with manure and leaves 86
Orchard grass 213
Orchards 416; report on 3
Organic chemistry, Liebig's, abstract of 395

P

Painting houses 143
Paper money, origin of 130; reform of 130

Patent machines 90
Peach trees, preservation of 477
Peas, field or Indian 251, 323
Peaty ground, mode of improving 378
Plant-lice 328
Plants, on preservation of races of by seeds 51; on improving races of 101
Plough, improper use of in cultivation of corn 475
Plough, steam, 457
Poisons, hints on 31
Polar plant, or vegetable compass 476
Potash, crude, recommended as manure 305
Potatoes, (Irish) culture and keeping 17, 131; raised from seed 64
Potatoes, sweet, another mode of keeping 187
Potatoes and oats in new land 206
Poultry, inquiries concerning 458
Prairies, western, some account of 189
Pruning fruit trees 222

R

Raspberry, culture of 490; ever-bearing 482
Reaping machine, of McCormick, its operation described, and use recommended 503
Red river, removal of obstructions in 144
Reports to Board of Agriculture—on live stock, fruits and fruit trees and vines 241; on the most important recent improvements of agriculture 257; on the Brandon farms and farming 274; on Nansemond county 298, 461; on Elizabeth City county 335; on the agriculture of Prince George county 383. 389; on the agriculture of Rockbridge county 458; on the obstacles to agricultural improvement caused by the legal policy of Virginia 511
Roots as food 251
Rotation of crops, remarks and inquiries concerning 94; answer to inquiries 115; remarks on different kinds of 175; argument for 299; rejoinder in opposition to the doctrine 354; replication on 399; the best kind for Kentucky 148
Rotation discussion, proposed to be resumed 499
Rust and mildew, report on 407
Rye, winter, for winter and early spring feed 369, 415

S

Salt marsh grass and mud as manure 81
Salt mine in Washington county, Va. 21
Saltpetre as manure 26
Sandy Point farm and farming (No. V.) 97, 217
Sassafras bushes 252
Science and agriculture 342
Sea devil, caught at Charleston 268
Season and crops 368
Seeding on green-sward furrows 440
Seeds, influence of their origin on the quantity and quality of crops 307; on changes of 473; of flowers, how to sow 138; onions 139; of mangel wurzel 139
Seeds and seedsmen, remarks on 138
Sheep, to guard from dogs 205; essay on proper management of in Kentucky 159
Sheep husbandry 82
Silk-culture of East Tennessee 119; near Baltimore 139
Skippers in bacon, to prevent 6
Slavery, white, in Great Britain 375
Slippery elm, flour of 70
Slugs destroying cotton, and suggestion of a remedy 310
Soap, receipt for making 69
Soils, remarks on 87; sandy, improvement of 447; of Delaware, and their formation 446; marshy, of Delaware 450
Sorrel, apparently nourished by marl 401; and the mistake corrected 402
Spelt or darnel 7, 8
Squirrels, emigration of, indicating a severe winter 492
Stall-feeding 341
Stercorized bark, &c. new resources for manure 158
Sugar, the production of 106; from corn-stalks 188
Sugar beet 135
Swamps, drainage of, opposed by the legal policy of Virginia 515

T

Tetter, cure for 18
Top-dressing on clover 86, 262
Trees, natural changes and successions of growths 361

W

Washington, General, letter of instructions from, to his overseers 484
Weeds, to kill 501
Weevil (black) French receipts for preventing 207
Wells, Artesian, in France, 240; Alabama 495
Wheat, on the adaptation of particular kinds to particular soils 89; on rolling in the spring 192; times of ripening of, in sundry years, and in different parts of lower Virginia 282, 394, 498; Mediterranean 511
Wheat crops of Virginia, causes of deterioration of 140
Wind pump for marl pits 236
Wire grass, growth of, kept down by top-dressing with leaves, 253
Wood ashes, their power of igniting 377
Worms in the heads of sheep 497
Worms, to kill 415

DIRECTIONS FOR THE BINDER.

The sheets containing the 'Essay on Calcareous Manures,' forming parts of Nos. 7, 8, 9, 10, 11 and 12, of this volume as issued, should be collected together, and, with the first and last sheets of the Essay, not yet printed, form the No. 12, of vol. x, Farmers' Register.

The concluding sheets of 'The Westover Manuscripts,' issued as parts of the first few numbers of vol. x., with the preceding portion of that publication, should be placed together in binding at the close of vol. ix.

THE FARMERS' REGISTER.

VOL. X. JANUARY 31, 1842. No. 1.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

THE BOARD OF AGRICULTURE, AND ITS DESIGNED ACTION.

A bill has passed the House of Delegates, but still remains undecided upon by the Senate, to pay for the personal expenses of the members of the Board of Agriculture, while the Board is actually in session, $3 per day, and the same rate of mileage pay, for travelling to and from the place of meeting, as is allowed to members of the Assembly. Even if this bill should pass the Senate, it will furnish nothing towards paying for the actual necessary outlay of money by members, in other, and as necessary expenditures; nor even for the smallest and most indispensable expenses of the Board itself, in stationary, clerkship, printing, &c. It is hoped however that even the continued existence of a great deficiency in this respect will not prevent the members performing the duty imposed on them, though the greater part of their expenditures, as well as their labor, may be at their own cost. But it will be absolutely necessary that at least the poor compensation proposed by the bill now before the Senate shall be given, or otherwise it is very certain that the law instituting the Board had as well be repealed *directly*, as in this indirect manner. However willing the members of the Board may be to make considerable sacrifices for the public benefit, it would be folly to expect of those the most remote, who have to travel more than 800 miles merely to attend and return from the annual meeting of the Board, can continue to do so at their own cost entirely. The editor, though a member of the Board, may be free to speak thus, because, being within 20 miles of Richmond, the mileage pay to him would be scarcely worth consideration. And the *per diem* pay (which for this first year would be but $18 for each one,) can scarcely be supposed to have much influence on his action, or that of any other member. If his own measure of pecuniary compensation were only in view, he would prefer that the services were to be, as under the original law, *altogether gratuitously rendered*. It is for other considerations, necessarily involving the very existence of the Board of Agriculture, and all the hoped for usefulness to be derived from even so imperfect a plan, that the bill before the Senate is to him of the slightest importance.

It may then be understood that the proposed action of the Board of Agriculture, as submitted to the legislature, (and published in the last No. of the Farmers' Register, p. 688,) is dependent upon the enactment of the bill before the Senate, or some other not less operative legal provisions. In case of such enactment, a circular letter of inquiry from the Board will speedily be printed, together with the plan of operations, and sent to sundry of the farmers of every county, whose public spirit it is hoped may induce their furnishing their aid to the great object of collecting and diffusing agricultural knowledge.

In pursuance of the general plan, (which the readers of this publication already have had before them,) the editor, as a member of the Board, as soon as *permitted*, will commence his share of the labors of personal examination and inquiry through some counties of the southern portion of the tide-water region of Virginia, which district has been assigned to his general supervision, by the arrangement and division of labors of the Board. It would greatly facilitate such labors of personal inquiry and examination, if, in advance, something were done by some of the farmers of each county (desiring such action) in preparatory operations. The preparation might be *individual* and *separate*, in noting observations on and answers to the published heads of inquiry—and also, *general* and *combined*, in founding an agricultural society, to meet the views and aid the operations of the Board of Agriculture. Where there is so much more to be done than any one member can possibly perform, (even if possessing far more ability and leisure,) of course the editor cannot count on being able to do more than point out a course of operations to others, and aid their more useful and instructive investigations. But so far as it is possible, he will be ready to meet the requisitions of the persons and communities which may appear to be the most ready to act effectually, and who may desire, and shall signify their desire, to have his personal co-operation. Such invitations are by no means desired as mere matter of compliment, or as evidences that the visits of the member of the Board on a tour of inspection would be *welcome*, and kindly received. No doubt on the latter head would be entertained by any one acquainted with old Virginia. But as a means of properly directing the few and feeble efforts which he may be enabled to make, the member will be aided much by any such positive *indications* of the places where those efforts

are most desired, and will be most certainly aided, and thereby rendered effective.

As was stated before, the constitution of a *working* agricultural society submitted at page 719, of last volume, if the general plan be approved, and whether amended or taken entire, may save much trouble in commencing and organizing societies. And at the time of such organization, or other designated time of meeting afterwards, it may be most beneficial to the cause that the visiting member shall then attend in pursuance of his mission; and it will be his pleasure, as well as duty, so to do, so far as the performance may be in his power. Though not authorized to speak in this respect but for himself, he presumes that the same remarks will apply generally to all his fellow members of the Board of Agriculture in regard to the duties assumed by them.—Ed. F. R.

MAIDSTONE FARMERS' CLUB.

Dr. Robinson concluded his course of lectures on chemistry as applied to agriculture, on Thursday evening. The concluding lecture proved, as we anticipated, of very great interest, as it embraced the testing of some of the fashionable artificial manures, the analysis of soils, &c. Those of our readers who had not the good fortune to be present will doubtless like to acquire a knowledge of some of the simple means used by Dr. Robinson to detect adulteration, more particularly as these require no previous knowledge of chemistry to enable any farmer to apply them. The lecturer's mode of testing nitrate of soda was the following. This salt is sometimes adulterated by a mixture of perhaps one-fourth of common salt (chloride of sodium,) which may be purchased at about one-fourth the price, and which it so closely resembles as to render it difficult to protect the admixture without some chemical process. Nitrate of soda, when pure, burns, if thrown on the fire or a pan of live coals, something like saltpetre. If it be adulterated with salt, however, it burns with a sharp cracking noise, which is greater or less in proportion to the quantity of common salt used, and the combustion is imperfect. Dr. Robinson observed that common salt was actually prejudicial to some soils, but even if it were not, there was no good reason why the farmer should give the same price for it as for nitrate of soda. Another test, which belonged rather to the higher branches of chemistry, was the following. Take a brachin of nitrate of silver (lunar caustic) and dissolve it in half an ounce of rain water. Dissolve a tea-spoonful of the suspected nitrate of soda also in rain water. Mix these two solutions together, and if a white curdly precipitate is observed to form, common salt is present. In this case the precipitate (chloride of silver) is insoluble in the acids, but would be soluble in strong ammonia. Nitrate of soda was also sometimes adulterated with sub-carbonate of soda, which can be obtained at about half the price. The mode of detecting this mixture is by dissolving some of the suspected crystals in rain water, and adding a little strong sulphuric acid (oil of vitriol.) If sub-carbonate of soda be present, effervescence will ensue. With reference to bone-dust, Dr. Robinson said that this was very frequently adulterated with wood dust and other substances, when sold in a very fine state. A simple mode of detecting the presence of saw-dust was by burning a portion of the manure, the bone would not burn, whilst the particles of wood, if present, would sparkle and burn. The farmers of Lincolnshire, partly from the fear of adulteration, and partly from bone-dust when ground too fine passing away too quickly, would never buy bone-dust when ground very fine. Dr. Robinson tested some adulterated bone-dust on some burning coals, and the coruscations of the saw-dust were clearly perceptible. He then applied the same test to some bone-dust which had been obtained from the Lenham mills, which was, however, found to be perfectly pure. Another test was the following. Bone-dust, when reduced to a fine powder, was perfectly soluble in hydrochloric acid (spirits of salt,) diluted with three times its bulk in rain water. Twelve hours were required for this experiment, at the end of which, if pure, the bone-dust would be completely dissolved. The lecturer produced a sample of the *guano*, recently introduced into this country from South America. It was the excrement of the flamingo and other birds which feed on fish, and which contained all the properties required in a fertilizer. It could be supplied at about 28*l.* a ton, and was drilled in with the crop in the same manner as bone-dust. This, if it came into extensive demand, would also most assuredly be subject to adulteration, which, however, would be very easily detected; for the guano, if pure, is readily and completely dissolved in diluted sulphuric acid. Dr. Robinson next proceeded to notice the mode of analyzing soils, which subject, however, we have only room to mention. It is almost needless to add that this course of useful, practical, and valuble lectures has given great satisfaction, and much information, to the members of the Maidstone Farmers' Club.

CROP OF CORN-STALKS.

From the American Farmer.

Permit me to mention an experiment made by myself at Washington, on the subject of fodder.—Noticing the statement made in the French periodicals, that the stalks of corn (maize) contained one half as much saccharine matter as cane, and knowing that my ancestors made their molasses during the revolutionary war from these stalks, I sowed four and a half bushels of common corn, broadcast, and harrowed in the same. This labor was easily performed by a single man with a team (including the ploughing) in a day. Having soaked the corn in saltpetre water, it took a rapid start, overtopped the weeds, and covered the ground with a forest of stalks. When fairly tasselled, I cut the same, which I fed to cattle, horses and hogs, both green and dry. If fed to swine after being cured, it was cut and fermented with chop

or bran. Being anxious to ascertain the quantity, I measured a few square feet of the stoutest. I found I had 5 lbs. of green fodder per square foot; this may not seem credible, and it is probably less than what would grow in rich lands at the west; if, however, we consider there are 43 560 square feet in an acre, we shall obtain 217,800 lbs., equal to 108½ tons of green fodder!

I cut the first crop the early part of July, and ploughed and sowed the same land again, and took a second crop two thirds as large, and even tried a third on the same land, but it did not reach over ten inches before the frost seized it. Persons who have only a small patch of ground may try this experiment to advantage and fill their barns with fodder.

In curing stalks, it is recommended to place the small end upon the ground, with the buts upward, to guard against the absorption of moisture from the wet ground. Whoever will try the experiment of cutting flowers, and putting some on damp flannel, or into water, and hanging up others in the sun, will see the advantage of curing fodder in the way I have mentioned. Should any fear the stalks would not stand upon the small end, a few rows could be left to support the remainder.—*Hon. H. L. Ellsworth.*

REPORT ON ORCHARDS.

From the New England Farmer.

The committee appointed by the trustees of the Society for the promotion of Agriculture in Massachusetts, consisting of Messrs. Welles, Prescott, Phinney, Codman and Quincy, having by their chairman examined the orchard of Capt. George Randall, report—

That it appears said orchard was set out in April, 1837. Its extent was about 3½ acres. The soil was good, but rather light, and was in a good state of preparation for the trees. The ground has been since annually cultivated for a crop; the benefit of which, both in the thrift and production of an orchard, seems generally agreed in. The number of trees was 212: their distance apart, 25 feet. There was a doubt with the committee whether the distance might not have been advantageously enlarged even to 35 or 40 feet. In four years they had acquired, several of them, near the roots, about thirteen inches in circumference, and at three feet above the ground, eleven inches by measurement. Many of the trees had extended in the growth of the limbs during the past season, from 15 to nearly 30 inches.

Mr. Randall's communication contains an account of a wash of oil soap, &c., which has been used by him on the trees in this orchard, since they were set out. If this application should operate to prevent the ravages of the borer, it will be of most important utility, as this depredator, with the canker worm, seems to threaten the very existence of our orchards. All which is well and fully set forth in the communication above alluded to, which your committee recommend should be forthwith published. And the committee further recommend that the premium of fifty dollars be awarded and paid to Capt. George Randall, for the best orchard.

All which is respectfully submitted by order of the committee, JOHN WELLS, *Chairman.*

New Bedford, 17th Aug., 1841.

To Benj. Guild, esq., Boston:—sir—I have a young apple orchard in the town of Rochester, Plymouth county, Mass., and ten miles from this place, which I wish to offer for a premium; *and do, by this letter*, offer, or apply for the premium, for the best orchard in the commonwealth, that has been planted out *four years* from the nursery.

Respectfully, your ob't. ser't.

GEORGE RANDALL.

The following comprises Mr. Randall's useful observations:

Description.

The extent of the orchard, 3½ acres; the number of trees, 212; their distance apart, 25 feet; the names of the apples or varieties, 57—as follows: Mela Carla; Flushing Spitzenberg; lady; doctor; English russet; Knight's pippin; crow's egg: Pumwater sweeting; red and green summer pearmain; pear apple; Amory; red doctor; Ruggles' sweeting; French nonpareil; Peck's pleasant; Gravenstein; black gellyflowers; Dawson; Dyre; Coney; Prince's Harriet; summer russet; orange sweeting; R. I. greening; superior sweeting (from the garden of the Hon. Jas. D'Wolfe, Bristol, R. I.); Æsopus Spitzenberg; blue pearmain; Mawney sweeting; Newton Spitzenberg; no core; yellow bellflower; Tewksbury winter blush; Wurner, (from Canaan, N. Y.); summer greening; codling; Porter; Roxbury russett; marigold; Hubbardston's nonsuch; Cooper; seek-no farther; summer sour; Ben; John goodwin; green Newton pippin; Pennock red winter; summer rose; Catlin; Baldwin; fall sarine; bellflower; winter sweeting; honey greening; lily pippin; early sweet bough; nonesuch.

Treatment.

The ground has been planted to roots, every year since, and including 1837, viz.: to potatoes, carrots, ruta baga, sugar beets and mangel wurtzel.

The manures used have been common stable; compost of stable, loam and swamp mud; lime compost, spent ashes, plaster, and a small quantity of saltpetre.

The trunks and lower limbs of the trees have been well washed with oil soap, sand and water, every spring and fall since they were planted out; after which a coat of oil soap has been put on with a painter's brush. The oil soap is made by refining and bleaching sperm oil, and is composed of from 33⅓ to 35 per cent. potash, and the balance sperm oil and impurities from the oil.

The first pruning was done the first of May last past; at which time every tree had the earth removed from around it, to examine for borers, not one tree was found to contain a borer, or any indication of one.

The soil, a sandy gravelly loam, and naturally light.

Observations.

I have noticed that shallow planting with all trees succeeds much the best, and can, I think, be accounted for philosophically. The roots are luxuriating in a good soil, and are more immediately under solar influence.

My mode of planting is as follows:—The mutilated roots of each tree are carefully cut off smooth;

even the small fibrous ones, and engrafting salve but over large cuts. The roots are immersed in water for above one half hour before planting, thereby inducing the mould or loam to become attached to them. The hole to be dug sufficiently large so that every root may extend without bending or being cramped. I put nothing around the roots but surface earth, and that carefully worked in by hand, each root and fibre thus laying horizontally and naturally. I use no manure in setting. One bushel of fine stable manure was put round each tree the first of November, and repeated for two years.

I prefer raising the earth around trees when first planted, above the common level, and thereby give them firmness, than to plant deep, placing a tree deeper than it originally stood, with no prospect of finding the surface earth, thus becoming a moss-covered and stinted tree, whose roots have been searching a cold and uncongenial soil, with little or nothing to give them vitality.

As to the time for planting, from the little experience I have had, I much prefer the spring of the year.

Much has been said and written in favor of autumnal planting. It may be that English authors have done much to encourage this opinion. In Old England I should expect them to succeed well in fall planting: they have but a few degrees of frost compared with New England.

In answer to your inquiries as to the oil soap, I say that from 8 to 10 lbs. of oil soap are put into a common pail, we put on a sufficient quantity of warm water, so that when commingled with the soap, it is about as thick or a little thicker than paint when mixed for use. With this pail of soap, thinned as described, the man having a small tin pail, or bag, or pocket, filled with fine sand, tied round his waist, with a coarse crash cloth and a paint brush, is ready for operating. He first wets his cloth with soap, then scatters on some dry sand, and gives the trunk and branches a good rubbing, after which, with a paint brush, he puts on a coat of the soap, prepared as above, equal to a thick coat of paint. It is well to select for this work the termination of a storm of rain, when the moss, or any roughness on the bark, will yield more readily to rubbing.

Respectfully, your ob't. serv't.

GEO. RANDALL.

The preceding useful observations were in part made in Mr. Randall's first application to the Secretary, Mr. Guild, for premium, and afterwards enlarged by the request of the committee.

EXHIBITION OF GRAPES TO THE LONDON HORTICULTURAL SOCIETY.

From the London Gardeners' Chronicle.

At an ordinary meeting in Regent street, Sept. 17th, we find the following report in relation to several grapes which were then exhibited:—

Mr. Roberts sent specimens of six different varieties of grapes, grown on young vines two years planted; and certainly for size, and weight of the bunches, we should think they have never been surpassed: a large silver medal was awarded them. The kinds were Cannon Hall Muscat; one bunch weighed 2 lbs. 3 oz., and some of the berries measured 1½ inch in circumference: an extraordinary bunch of the white Nice, which weighed 7 lbs. 12 oz., was not quite ripe, and from its usually being brought to the table in that state, it is little esteemed; when, however, it is well ripened, its berries assume an amber tint, and become high flavored: black Hamburg, black Prince, black Damascus, and black Morocco; a bunch of the first weighing 2 lbs. 5 oz.; of the second, 2 lbs. 15 oz.; of the third, 1 lb. 11 oz.; and of the fourth, 2 lbs. 7 oz. Mr. Stewart had a Banksian certificate given him for his black Hamburg grapes, and a seedling with small round berries. Mr. R. Buck sent a bunch of Cannon Hall Muscat, which weighed 1 lb. 11 oz. The grapes from Mr. Roberts were as fine specimens of cultivation as are ever seen near London, but his Hamburgs wanted color; this defect was avoided in Mr. Stewart's, whose black grapes were as jetty as they ever can be in the brightest and most sunny season. A bunch of Muscat of Alexandria, from A. Brooke, Esq., weighed 1 lb. 12 oz., and was in perfect maturity: a Banksian certificate was awarded for it.

THE IMPORTANCE OF ALKALIES IN SOILS.

To the Editor of the Farmers' Register.

Prospect Hill, Ky., Jan. 1, 1842.

The following quotation is from Liebig's late work on organic chemistry. "A soil, which has been exposed for centuries to all the influences which effect the disintegration of rocks, but from which the alkalies have not been removed, will be able to afford the means of nourishment to those vegetables which require alkalies for their growth, during many years; but it must gradually become exhausted, unless those alkalies which have been removed are again replaced; a period will therefore arrive, when it will be necessary to expose it from time to time to further disintegration, in order to obtain a new supply of soluble alkalies. For small as is the quantity of alkali which plants require, it is nevertheless quite indispensable for their perfect developement. But when one or more years have elapsed, without any alkalies having been extracted from the soil, a new harvest may be expected."

"The first colonists of Virginia found a country the soil of which was similar to that mentioned above; harvests of wheat and tobacco were obtained for a century, from one and the same field, without the aid of manure, but now whole districts are converted into unfruitful pasture land, which, without manure, produces neither wheat nor tobacco. From every acre of this land there were removed, in the space of one hundred years, 1200 pounds of alkalies in leaves, grain, and straw; it became unfruitful, therefore, because it was deprived of every particle of alkali, which had been reduced to a soluble state, and because that which was rendered soluble again, in the space of one year, was not sufficient to satisfy the demands of the plants. Almost all the cultivated land in Europe is in this condition; fallow is the term applied to land left at rest for further disintegration. It is the greatest possible mistake to suppose that the temporary diminution of fertility, in a soil, is owing to the loss of humus; it is the mere consequence of the exhaustion of the alkalies."—p. 195-6.

Although the facts stated in the latter paragraph of the above quotation may not be entirely correct, yet it is worthy of inquiry whether the diminution in the fertility of the lands of lower Virginia may not, in a considerable degree, have been caused by the exhaustion of the alkalies, which existed in the soil, at the time it was first brought into cultivation.

According to Liebig, "the developement of a plant requires the presence, first, of substances containing carbon, and nitrogen, and capable of yielding these elements to the growing organism; secondly, of water and its elements; and, lastly, of a soil to furnish the *inorganic* matters, which are likewise essential to vegetable life."—p. 56. Water is composed of hydrogen and oxygen, and as plants are capable of decomposing and assimilating its elements, (pp. 122 and 125,) there can never be a deficiency in the supply of these to growing vegetation, except in time of drought. During the early growth of plants, carbon is furnished by the humus of the soil, in which they grow, but after they have developed their leaves an abundant supply of carbon is obtained from the atmosphere, by means of their absorbing power. This supply is so great, that in the opinion of Liebig, (p. 106,) they no longer acquire any from the soil, and return even that which they had extracted, during the formation of their first leaves. The remaining *organic* substance, essential to the growth of plants, is nitrogen. This, according to Liebig, is furnished, to some extent, from the atmosphere, in the form of carbonate of ammonia. This substance is very soluble in water, and consequently combines with the moisture of the atmosphere, and is brought down to the earth with the dews, rain and snow, and thus furnishes, to some extent, this necessary element for the nourishment of plants. The quantity derived in this way, though considerable, is not sufficiently ample to produce a flourishing and vigorous growth of plants. To preserve the fertility and productiveness of soils, the *deficiency of nitrogen* must be supplied by the application of putrescent manures, which abound in this ingredient. According to Liebig, this may be so easily effected, that by the application of human excrements, "using, at the same time, bones and the lixiviated ashes of wood, the excrements of animals might be completely dispensed with."—p. 242.

From these views it is quite apparent, that but little effort is necessary to prevent our growing crops from suffering from a deficiency in the principal *organic elements*, which constitute the appropriate food of plants.

But several *inorganic matters* "are likewise essential to vegetable life." Liebig informs us that "most plants, perhaps all of them, contain organic acids of very different composition and properties, all of which are in combination with *bases*, such as *potash*, *soda*, *lime*, or *magnesia*. These *bases* evidently *regulate* the formation of the acids, for a diminution of the one is followed by a decrease of the other."—(p. 148.) Here are four of the *inorganic* substances which are most essential to the growth of vegetables. They are, it is true, combined with *organic* acids, which are necessary to fit them for assimilation, but the quantity of the acid is always regulated by the *base*, so that, if the latter be diminished, the former will be decreased in a corresponding degree; and whenever a *base* is present the acid will be supplied. We have then but to furnish the soil with potash, soda, lime, and magnesia, (if they do not already exist,) when the necessary acids, to fit them for assimilation by the growing plants, will combine with them.

The inorganic substances, mentioned above, are all important in constituting a good soil, but magnesia is, perhaps, less so than either of the others; yet even this is essential to the vigorous growth of many vegetables, for, as we are told by Liebig, "all seeds of the *graminœ* contain phosphate of magnesia," (p. 93,) and that without this substance "the seeds of corn (wheat) could not be formed."—p. 201.

Many soils are, by nature, abundantly supplied with carbonate of lime. But when it does not exist, in soils, it is very important that it should be supplied. Fortunately, the extensive banks of shell marl, in lower Virginia, afford the means of doing so, and no reasonable expense should be spared in accomplishing an object so important in the renovation of exhausted soils.

Vegetables of all kinds contain, in their composition, more or less of the alkalies. It is very clear, therefore, that this ingredient is indispensably necessary to their growth. If a soil has been entirely exhausted of the alkalies, it must necessarily be completely barren. If it has been only partially exhausted, it will be still capable of producing a vigorous growth of those trees and plants which require only a small supply of the alkalies. But the growth of those which require a large supply must necessarily be much stinted. Thus forest trees, the leaves of which are renewed annually, require from six to ten times more alkalies than the pine or fir tree, and hence pines will grow vigorously in a soil, where other trees cannot attain maturity. (p. 198.) So 100 parts of wheat straw will yield of ashes 15.5 parts, whilst that of barley yields 8.54, and of oats only 4.42.—p. 199.

Plants of the *leguminosæ* family require very small quantities of the alkalies. Buckwheat, beans, lucerne, clover, and lentils yield less than one per cent. of ashes.—p. 204.

These facts are abundantly sufficient to show that the quantity of alkalies, in soils, should be in proportion to the kind of crops intended to be produced. If they exist only sparingly, those crops should be avoided which require a large supply, unless the soil should have been furnished by artificial means. Wheat requires not only more of the alkalies than any other crop, but also a considerable quantity of the phosphates, and is therefore a very exhausting crop.—p. 205.

The alkalies being so necessary to constitute a good soil, the question arises how this ingredient is to be supplied to those soils, from which it has been nearly all extracted. This is to be accomplished first by ceasing to cultivate those crops, which require a large supply of the alkalies; and secondly, by furnishing by artificial means, those soils which are deficient, with a due proportion of these essential ingredients.

Soils are supplied with alkalies, in the natural way, first, by the disintegration of rocks, (p. 195-6) and secondly, by water evaporated from the sea, and falling in the form of rain, snow and dew (p. 160 166-7.) But the supply from these sources is too slow and gradual to be relied upon exclusively, and therefore great efforts should be

made to increase the quantity by the application of ashes. Lixiviated ashes are valuable, as they contain silicate of potash and salts of phosphoric acid, (p. 228); but those which have not been lixiviated are much more so. Both kinds are so highly esteemed, as manures, in Germany, that they are transmitted to the distance of twenty-four miles. In situations, which admit of water or rail-road transportation, they might be carried to still greater distances, with decided advantage.

It is not very material whether potash or soda is furnished to soils, from which the alkalies have been extracted, for these *bases* are readily substituted for each other, where there is a deficiency of either, (p. 149.) Potash may even be substituted, in many cases, not only by soda, but also by lime and magnesia, (p. 200.) This shows what a powerful effort is made by nature to supply plants with alkalies, by substituting alkaline earths, where they are entirely deficient.

I have heretofore adverted to the high estimate formed by Liebig, as to the value of human excrements as a manure. Of these urine is by far the most valuable part. Urine contains several ingredients, which are extracted from the ashes of wood, such as *sulphate* of potash and soda, and *phosphate* of soda. It contains also phosphates of ammonia, magnesia and lime, and several other valuable ingredients for the nourishment of plants. Liebig estimates 100 parts of the urine of a healthy man to be equal to 1300 parts of the fresh dung of a horse, (p. 240.) The saving and application of this manure is, therefore, of very great importance. But if not properly taken care of it is subject to great loss. During putrefaction, carbonate of ammonia is formed, which volatilizes, and passes off in the form of gas, and the urine becomes alkaline. In this way nearly one half of the urine is lost, (p. 237.) Liebig informs us that the carbonate of ammonia, formed during putrefaction, may be converted into a salt, and thus fixed in the soil. This may be effected by strewing a field with gypsum, and then sprinkling it with urine. It may also be neutralized and converted into a salt, which has no volatility, by the chloride of calcium, sulphuric or muriatic acid; or super-sulphate of lime, (p. 238.) As the value of this manure will be so greatly increased, by preventing the ammonia from escaping, which is formed during the putrefactive process, this should never be neglected.

Yours, truly, A. Beatty.

TO KEEP SKIPPERS FROM BACON.

It is stated in the "Plough Boy," an agricultural paper recently commenced in South Carolina, that if a small piece of sulphur is thrown on the fire every day the bacon is smoking, it will effectually prevent skippers and bugs from entering. We consider this an important matter, and we are strongly disposed to believe the remedy a good one.—*Ex. paper.*

The remedy may be, and no doubt is, a good one, but we doubt its propriety, believing that the fumes of the brimstone will impart a bad flavor to the bacon.—Ed. Ky. Far.

[If the remedy be effective in preventing skippers, no fear need be entertained of a disagreeable odor remaining. We have heard that as good effect may be produced by throwing a few pods of red pepper on the fire once in two or three days during the smoking of the bacon. The latter plan has been tried several years in our own house-keeping; and whether that or some other cause operated, there were no skippers in the bacon. In one case, salted fish in barrels, placed in the meat-house after the smoking was finished, was full of skippers, while the bacon remained free.—Ed. F. R.]

PAPERS ON CHEAT AND SPELT, OR DARNEL.

[In our recent remarks on spelt, we had to refer to the following articles from memory alone, not having seen them since soon after their first publication, and having lost our volume of the American Farmer containing them. Our friend, Dr. G. B. Smith, the then editor of that work, has since kindly supplied the lost volume; and from it we copy below the whole correspondence which brought out the before published facts in regard to darnel, and its recent introduction into this country. It should be observed, that the writing of the first of these articles, was induced by a preceding long discussion in the American Farmer on the convertibility of wheat to cheat.—Ed. F. R.]

Prince George Co., Va., June 6, 1832.

Mr. Smith.—Notwithstanding all the facts and arguments that have been brought forward in the controversy on the origin of cheat, that has lately occupied your columns, it is highly probable that the writers on both sides, and their readers, without an exception, retain the same opinions as at first. We are always too partial to the reasons that support our side of any question, to allow fair play to those on the other; and thence it follows, that when the reasons are strong, yet vulnerable on both sides, no amount of authority, or extension of argument, can convert partizans, or establish the truth. Believing it, therefore, utterly useless, I shall abstain from adducing the reasons that have satisfied my mind that cheat is not the product of degenerated or damaged wheat. But however ineffectual argument may be, a few experiments, made and observed carefully, will serve to decide this interesting and important controversy; and I invite your correspondents, and others who feel interested in the decision, to aid in this mode of obtaining it. Perhaps more satisfactory experiments than the one I shall propose, may be thought of by others; but this alone will suffice to prove that wheat may be changed to cheat, if indeed that opinion is correct.

Select a soil supposed to be the most favorable to the production of cheat. This I consider to be on some sandy slope, which is subject to be too wet in winter and spring. Let a small space, (now clear of growing cheat) be broken up and stirred at different times, from August to October,

so as to cause every seed in the soil to sprout, and then to be destroyed. At the time of sowing wheat, mark off a square of ten or twelve feet accurately into checks of a certain size, (say eight inches,) and at every crossing of the lines plant three grains of imperfect wheat. The grains should be dropped together in a hole made by thrusting a small stick to the proper depth. In the spring, let the plants be cut or grazed once or oftener, but not so late as to prevent the formation of seed stalks. All the causes that are severally supposed to produce cheat would here operate; and if any stalks of cheat should be produced, their situation and number would clearly show whether they sprung from the grains of wheat or not.

Being entirely ignorant of botany, I am not sure that all of us refer to the same plant when we speak of cheat. That name here is sometimes made to include the two very different plants, which will accompany this letter; though one of them (marked No. 2) is now generally distinguished by the name of spelt. The latter is by far the worst pest of the two—and though now less abundant, is, like the cheat, (No. 1,) increasing in spite of all the means yet used for its destruction—and both together threaten the most serious injury to the wheat-grower. The general opinion is, that both these plants are produced from wheat, by the operation of some of the various causes that have been urged by your correspondents who believe in such transformations. But no reasons have been offered, why wheat should sometimes change to cheat, and sometimes to spelt—nor why neither should have been sufficiently plenty twenty or twenty-five years ago, to be a noticeable evil in our crops, though our cultivation then was even more slovenly than it is at this time. The grains of cheat being considerably smaller, and specifically lighter than wheat, may be mostly got out of a crop by good fanning and losing much good wheat with it. But the grains of spelt are so nearly of the same size and weight with those of wheat, that it is impossible to separate them by either the fan or the screen.

Whenever our negligence has permitted cheat and spelt to be scattered over our farms, it seems almost impossible to stop their growth, even to those farmers who suppose that they never are produced except from parent plants of the same kind. The purchase of pure seed wheat (which is already extremely difficult) does not remedy the evil, as the seeds of both cheat and spelt will often remain uninjured a year, or perhaps much longer, without germinating, when buried deep by the plough. But with those who believe that wheat changes to cheat and spelt, it is obviously *impossible* to get rid of the evil; and that opinion is calculated to repress every effort for that purpose. Hence the necessity of deciding by fair and careful experiments, whether these pests are legitimate or bastard vegetable products. E. R.

—

Remarks on the above, by the Editor of American Farmer.

The specimens enclosed in the above communication were, *a head of cheat*, (*Bromus secalinus*,) and *a head of darnel*, (*Lolium temulentum.*) The latter is the first specimen we have seen of the plant, and were not before aware of its having made its way across the Atlantic. It is the plant which the English farmers suppose originates from wheat. We have also found a specimen of *Bromus mollis*, soft brome grass, which some suppose originates from timothy. It resembles cheat very much, except that it is more delicate, with smaller heads and seeds. It is somewhat curious that this timothy cheat, as it is called, (soft brome grass) was found in a wheat field, where there never had been a spear of timothy.

Apropos. A farmer who is a firm believer in the degeneracy of wheat to cheat, informed us that he saw a whole field of cheat, and that the owner was cutting it for hay. It proved to be a fine crop of rye grass—*Lolium perenne.*

—

Poplar Grove, June 30, 1832.

Mr. Smith:—I herein enclose you two heads of darnel or cheat, the one with a head resembling oats, is that kind which has been known in this section of the country, time immemorial—the other is a plant which from its peculiar form of growth, resembling the teeth of a saw or notches on a board, has acquired the name of the *notch* darnel. It first appeared on Kent Island, soon after the British encampment on that Island, during the late war, from whence it has been carried by birds, and has spread considerably elsewhere. It has a larger and heavier grain than the common darnel, and hence it is with more difficulty separated from the wheat in winnowing. How far its more farinaceous character renders it a better food for stock than the old darnel, I know not. Like the Hessian fly which soon appeared after the encampment of the British on Long Island, it is believed to have been introduced by them; but whether with more truth or not, I am unable to say. I should be glad, if you can furnish them, to have the true botanical names of both these plants, and also the vulgar names they are known by in England; where I presume they are both known, and where the latter may probably be in cultivation for some edible purpose, as I believe it to be extremely productive.* It has long been a matter of surprise to me that intelligent farmers, and particularly my highly intelligent friend Muse, should believe that wheat is capable of turning to darnel. It is against the order of nature, and I venture to assert, it will be against all *fair* experiments to produce the change. It cannot, in my opinion, be in the power of man or beast to effect it. If you sow *wheat on a clean soil*, you will have wheat, and if you sow darnel you will have darnel, without any danger of its *turning back*, to the end of time. A sound rule ought to work both ways; but you can no more convert darnel into wheat, than wheat into darnel.

* * * * *

T. Emory.

—

By the Editor of American Farmer.

We are much indebted to Col. Emory, of the Eastern Shore, of Maryland, for the communi-

* Is it German speltz, tares or vetches, neither of which plants, although grown and known in Europe, I have any knowledge of? The samples I send are unripe.

cation on another page relative to cheat. The "heads of darnel" enclosed in the letter, are those of common cheat, and the darnel of the English. Cheat, in England is called smooth rye; in America, cheat, chess, and sometimes darnel. Its botanical name is *Bromus secalinus*, belonging to the 3d class and 2d order of Linnæus. But there is another species of bromus or cheat very common in this country, and so nearly resembling common cheat that it is often mistaken for it. It is the *Bromus mollis* of Linnæus—soft brome grass of the English. The only material difference between this plant and the true cheat, is the slenderness of its growth and smallness of its seeds, by which, when together, the two species are easily distinguished. The soft brome grass is supposed to spring from degenerated timothy, by the believers in such changes, as it is most usually found in grounds adapted to timothy.

Darnel, the kind mentioned by Col. Emory, as having first appeared in Kent Island, (in the Chesapeake bay) soon after the British encampment on that island, of which Col. E. sent a specimen, is the *Lolium temulentum* of Linnæus, belonging to the 3d class and 2d order of the Linnæan arrangement. It is of the same genus as the celebrated and excellent perennial rye grass, and this latter and eight other species are all called darnel in England. Some farmers in England, and other parts of Europe, still suppose that this darnel originates from degenerated rye and wheat, whence probably the common name of rye grass.

By some persons in Virginia, the darnel (lolium temulentum) is called *spelts*, but improperly, as there is a species of wheat, *triticum spelta*, which is called *spelt* in England; but no other plant is called by any name resembling it. Spelt is grown in some parts of Germany, on high land, where common wheat will not ripen. It is improperly placed in the genus triticum, (wheat,) as it has distinct generic characters. It has a stout straw, almost solid, with strong spikes or heads, and chaff adhering firmly to the grain. The grain is light, yields but little flour, and makes poor bread.

The tares or vetches of England, are very distinct plants from cheat and darnel. They are the *Vicia sativa* of Linnæus, and in their characters and habits resemble the common pea.

We rejoice that Col. Emory has been able to trace the origin of this new pest, (darnel,) as otherwise our wheat would have been degraded by another suspicion of its mutability. It has, however, already suffered in this way, as will have been seen in an article in the 16th number of the Farmer, page 134. The origin of darnel having been traced to Kent Island, its existence there is easily accounted for:—it was doubtless brought there in the horse provender, in the oats; and as it is a common practice to feed the *tailings* of wheat to horses, it is very probable that quantities of that article were sent over for the use of the British cavalry horses, and thus left on the island where the army encamped.

We are glad to add the name of so respectable a gentleman as Col. Emory to the list of those who believe in the immutability of wheat, and of every other created thing. Vegetables may be improved in their qualities, may be rendered worthless, and may be hybridized, by high or low cultivation, and by cross impregnation, but their distinctive characters, their organic structure, must always remain the same—without a shadow of change. The short fine hair of the leaves can no more be taken from cheat nor added to wheat than a regular ear of corn can be produced upon broom corn; than watermelons can be produced from pumpkin vines, or any other such irregular operation.

—

Prince George County, Va., Oct. 23, 1832.

Mr. Smith:—When I sent to you for examination a head of *darnel*, or what is here called *spelt*, I was surprised to learn from your answer that its existence in this country is so limited, as it must be, as it had not before fallen under your observation. It is a subject for congratulation, that our country generally is yet free from the worst pest that attends the cultivation of wheat. As soon as I was informed by you that our *spelt* was the English weed *darnel*, I immediately attributed its presence here, to the importation of English race-horses, which have been frequently landed at city Point in this county; and darnel was no doubt brought in their oats and litter, and by that means scattered over our country. By the way, a Spanish thistle full of burs and sharp thorns, was brought to the same place, and also to Petersburg, in the fleeces of Merino sheep; and having been permitted by neglect to spread, threatens to add another serious and endless annoyance to our farming. Though darnel has not been known here so long as twenty years, as a considerable injury to wheat, yet the opinion is already prevalent that this plant, like *cheat*, is merely degenerated wheat. These erroneous opinions are calculated to repress all vigorous efforts to root out the evil; and if darnel should be allowed to spread throughout the country, it will be impossible to get rid of it. By great care, perhaps we may relieve ourselves of these pests, if the attempt is made without more delay. Nothing will clear land already set with darnel, but carefully pulling every plant out of the crops of wheat, and sowing perfectly clean seed.

Darnel is poisonous in a very high degree. I have heard from good authority, of three several cases in this county of persons being made alarmingly ill by eating a single meal of bread made of wheat containing a large proportion of darnel. They were immediately seized with violent sickness of the stomach, convulsed limbs, &c. and it was thought by those who witnessed the effect, that nothing but the speedy use of active medicine, saved the lives of the persons so affected.

We farmers are apt to complain of the millers, for the many and strong objections that they make to the condition of our wheat when offered to them for sale,—and we complain with some reason, because such objections are urged irregularly, capriciously, and are very much influenced by the demand and price. But if some fixed and regular rule could be adopted, which would impose a heavy but uniform penalty on the farmer for every kind of impurity in his wheat, I have no doubt but it would be ultimately, if not immediately, beneficial to every farmer, as well as to the miller, and to the whole region of country in which the rule was adopted, by raising to the highest grade the character of its wheat and flour. When wheat of average quality sells for one dol-

lar the bushel, a crop free from all impurity ought to be worth ten cents more; and the foulest that would be considered "merchantable," would be worth ten cents less—making a difference of twenty cents between the best and worst quality. If prices were always proportioned to these values, the difference would be a sufficient premium for the care necessary to keep crops clean. But unfortunately such is not the case. The purchaser will readily admit that there is this great difference in the intrinsic worth of the best and worst wheat; but his prices must be regulated by his expected sales—and he cannot afford to add to the average price above five cents for the best, nor need he deduct more than the same amount from the worst. Thus the average quality of wheat in any certain market, serves in a great measure to fix, or to approximate to it, the prices of both the best and worst crops. Therefore, the most slovenly farmer gets for his wheat five cents more than its intrinsic value, and he who sells perfectly clean wheat gets five cents less. This state of things amounts to a bounty being offered for foul crops.

A remedy for this evil, and a great and rapid improvement in the general quality and cleanness of our wheat, might probably be effected by something like the following plan. Suppose the millers of some considerable wheat market, together with some of the principal farmers who usually supply them, to consult and agree upon the full value of the injury that would be caused to clean wheat, by admixtures of either cockle, garlic, cheat, darnel, &c. For example, it might be agreed that, in a sample of one pound of wheat, it should be considered that ten grains of wheat should be deducted as a fair equivalent for the presence of one grain of darnel, or for two of garlic, three of cheat or cockle, or for ten of oats or rye, besides all the impurities so found; and that a proportional deduction shall be made from the price offered for pure or clean wheat. The selection of fair samples, and the trial of them, would be troublesome, it is true; but much less so than the usual chaffering, and the frequent dissatisfaction caused by the want of fixed and certain rules.

Let us now suppose some such *tariff of filth* to be in operation, and observe its probable effect. Suppose that, without such regulations, the demand for flour would have fixed the price of wheat of middling or average quality at one dollar; and that the amount of impurities in the sample, rated as proposed, would take off ten cents from the bushel. It may be considered by many that this would reduce the market price to ninety cents. Not so: the effect would be to *raise* the market price to one dollar and ten cents, which would be obtained by the few who could offer clean wheat—and from which the seller of average wheat would still obtain one dollar, after having ten cents deducted—and the foulest crops might suffer a deduction of twenty to thirty cents. The average of all the prices would remain the same, but would be equitably proportioned to the value of each crop—and thus hold out the strongest inducements to every farmer to aid in improving the quality and character of the wheat of the country at large.

Unless most of the farmers of a particular district unite in the endeavor to root out cheat and darnel, it will scarcely be possible for any one to succeed in the attempt. Persons who have always sown clean wheat, (or at least supposed so,) cannot conceive how the seed of cheat or darnel could get upon their fields, and therefore attribute their appearance to a transformation from wheat. But, without resorting to this mode of explaining the fact, there are abundant means by which a farm may be supplied with these pests, if they are abundant in the adjacent country. From various reasons, most farmers frequently procure seed wheat by purchase—and it is already almost impossible to obtain any near this county, entirely free from both cheat and darnel. It is true that there are plenty of crops that are *called* clean—and few will deny them that character if they contain only one grain of cheat in a handful of wheat; yet that small proportion would furnish a flourishing plant of cheat for every cast of the sower, and insure a much greater proportion in the next crop. Being subject to none of the many disasters that destroy so large a proportion of the plants of wheat, the hardy cheat and darnel show an increase of quantity in every successive crop, though much the greater part of their seeds are fanned and screened from the seed wheat. But this is not all. The grains of cheat and darnel left by the fanner in the chaff, and *tail-ends* wheat, are given in feed to hogs and other stock; and from their hard and firm covering, they frequently, if not generally, pass through the animals uninjured, to grow wherever dropped. This perhaps prevents darnel being as poisonous to beasts as it is to man. Many of both these seeds are also left in the straw, and carried out with the manure made from it. If the manure is well heated by being heaped to ferment, only all the seeds in the outer parts of the heap will germinate—or the whole will, if carried out in unrotted manure. If it is ploughed in a good depth, the seeds of darnel and cheat will remain without sprouting a year, (as I have experienced,) and perhaps much longer, and grow when afterwards brought near enough to the surface. Thus, when manure containing those seeds is ploughed in for corn, the best tillage and weeding may not prevent their springing plentifully among the succeeding crops of wheat. For these and other reasons, if cheat and darnel get on any part of a farm, they will soon spread to every acre, if great care is not used to arrest their progress.

But suppose a farmer by extraordinary care and labor to eradicate these pests, and to avoid every act by which he may introduce them again. Still by various means he will be in danger of receiving other supplies. He cannot avoid visits from his neighbors' horses, oxen, and sometimes stray hogs, carrying the seed in their bowels, and bestowing them wherever they go. Nor can he avoid lending his wheat bags, and his fanner, all of which are likely, and the last is sure, to be returned with cheat or darnel, unless the contents are sown over his farm, as they are jolted homeward. Your regular borrowers of fan-mills are generally well stocked with cheat and darnel. These chances for a supply are greatly increased if a private road, for neighborhood use, passes through a farm; and still more, if a stream, subject to overflow low grounds, and which has traversed other farms above. E. R.

For the Farmers' Register.

GRASSES AND GRASS CULTURE OF FRANCE.

Mr. Editor—Here is a brief account of some of the grasses which are mostly used in France, taken from 'Le Bon Jardinier,' for the 'Farmers' Register.'

Ivraie vivace, Ray grass of England, Lolium perenne, Darnel. Of all meadow grasses, this is that which is most generally sown in France. It is very much used under the name of *Gazon Anglais*, (English turf,) to form a covering of green. In farming, the results that are obtained from it are infinitely various, on account of the climate, the soil, and other local circumstances, which is without doubt one of the causes of the great difference of opinion in regard to its merits. In general one may admit that the ray grass is not (in France particularly) a good plant for mowing. There are however exceptions; and one often sees it in low and moist meadows, from two to three feet high, vigorous, well provided with leaves, and not coming to maturity sooner than the other grasses. In such cases it should be esteemed, and may be regarded as equal to any hay that you may find. One should then partially use it in sowing similar meadows; but without these favorable circumstances the hay is bleached, and is perfectly dry, and I have seen horses refuse it, although cut when just commencing to flower. It is then as pasturage that it is desirable to use it on all lands where it cannot obtain sufficient humidity to produce good hay. On level lands, particularly on those which are rather stiff than light, it will render good service in this manner. Its precocity, its facility of recovering after severe grazing, and of shooting again and strengthening itself, although much eaten and trampled, together with the nourishing and fattening qualities of this grass, are well known by experience, and assign it a useful place among grasses. In situations and on lands that are dry and scorching, the ray grass, whether as hay or as pasturage, is but an indifferent resource; and in every case its success and its product are always proportioned to the degree of humidity of climate and of soil. In England, where for this reason its success is much more general than in France, they often form, with a mixture of ray grass and red or white clover, a meadow destined to last from two to four years and even more. If one sows a field in ray grass, the addition of these two plants in small proportion is always desirable. For pasturage, they add only the white clover; but one might add with good effect the *Tréfle fraise*, and also the *Lothier corniculé*. One hundred pounds of seed are amply sufficient for a hectare of meadow land; for grazing, twice that quantity is necessary. They sow it in February and March, or in September and October. But where a small piece of good land is cultivated, and is to be irrigated with care, it may be sown at any season of the year.

Ivraie d'Italie, Ray grass of Italy, Lolium Italicum. Switzerland and the northern part of Italy have recently furnished us this grass, which has been cultivated for some years with much success in those countries. Some regard it as a variety of the ray grass, (Lolium perenne,) others as a distinct species. This last opinion appears to me to be the most probable: the plant, although resembling our ray grass in the head, differs widely in other respects. It does not mat itself on the ground as does our variety. Its shoots and its leaves, rising up more perpendicularly, are larger and of a more bluish green, the stalks more elevated, and the flowers always bearded. The *Ivraie d'Italie* has also a disposition to put out and grow again after it has been mowed, which is altogether foreign to the other variety. They announced it as vivacious, and lasting for three or four years, but from the observations of Mons. de Dombasle, and those which I have made myself, or which have been communicated to me, it does not appear that it affords good produce for the sickle for more than two years. It is also objectionable because it is liable to the mildew and the spur. Opinion is not yet decided as to the nature of the soils to which it is best adapted, and particularly as to the power it possesses of succeeding on dry and indifferent lands. I could mention many remarkable instances of its success, but the greatest number of attempts give me reason to believe that it requires a moist soil, or at least a cool one, which must be at the same time rich. It is probable that it will be a long time before we can arrive at any definite conclusion about the habits of this plant, because it offers strange inequalities and disparities in its vegetation and its results. Some persons attribute this to a difference of varieties; already speculation has seized this idea, to offer seeds of the really good varieties of the *Ivraie d'Italie* in opposition to what are bad. I do not believe the distinction well founded; but when I have studied it by comparative attempts, I shall endeavor to make public any conclusions that I may derive from my essays. It is however certain, that, whenever the *Ivraie d'Italie* thrives and flourishes, its produce and its vigor of vegetation are truly wonderful. I have known a piece of ground sown in May to give in the same year three good mowings of hay. The rapidity of its growth prevents its being sown with the small grain crops, as it will outgrow them, and perhaps stifle them. It is therefore necessary to sow it alone in the autumn or in the spring, at the rate of from forty to fifty kilogrammes per hectare.

Panis élevé, Herbe de Guinée, Panicum altissimum, Guinea grass. The great reputation of the Guinea grass in America has long since induced attempts to be made to introduce its culture into France. These experiments however did not succeed, probably because they were made with seed of plants which came from the Caribee islands; but, since 1820, some seeds obtained from Carolina have had much better success. At Paris and at Geneva, the plants which were obtained from these seeds have withstood the severity of our ordinary winters, and some resisted the rigorous frosts of 1820, 1830, 1832. Mons. le Compte de Mosbourg has sown it with success on a lot in the environs of Cahors. The plant, although producing but few seeds, has with me for many years propagated itself, and may be looked upon as having become acclimated. In America the Guinea grass is propagated by slips, which are obtained by separating the tufts that become very large, each one affording a great number of cuttings. This method is equally practicable here. If one wishes to raise it from the seed, it is necessary to sow them about the last of April or first of May, on a bed with a southern exposure.

In June they lay the border off in rows twelve or fifteen inches apart. The second year it attains perfection, and presents a mass of stalks and leaves of an extraordinary abundance, and often more than four feet in height. It is principally used as green food for cattle and horses. The name, Guinea grass, has been improperly applied to some other plants, particularly to *Panicum virgatum* and the *Panicum coloratum*.

Paturin, Poa des Prés, Poa pratensis, Spear grass. Among the *paturins* there are many plants interesting in different respects, but especially on account of the fine quality of the forage which they afford. The variety known as the *Paturin des prés* is perhaps the most difficult to appreciate. Few grasses are so common, or present themselves under so many different aspects. You will see it dwarfish and arid on the sides of roads and ditches, and large and succulent on moist meadows, but always very precocious, and very much inclined to spread. These two peculiarities render it often more obnoxious than useful in mixtures formed by accident, and should prevent is being employed in the formation of meadows without circumspection; although its hay has the reputation of being very excellent. It will be best, perhaps, to sow it alone, or to associate it only with the fox-tail, (*Alopecurus pratensis,*) and the common paturin, in moist lands, which, although rather later, yet require to be cut about the same time; and on dry soils with the *Dactylis glomerata* and the *Avena elatior*, and a little of the *Anthoxanthum odoratum*, and some of the leguminous grasses, taking care in the last case to mow it at an early season. When sown alone, from thirty-five to forty pounds of seed per hectare are requisite.

Le Paturin commun, Poa trivialis, Pasture grass, is as common as the preceding, and grows like it on lands of very different nature, it abounds on lands that are dry, and in artificial meadows, and yet humidity is so favorable to it, that it is often found in situations so moist that they are almost aquatic. I prefer it to the *Poa de prés.* It is necessary to mow it early, because it will wither very quickly after the flowering is over. About thirty pounds of seed per hectare are sown.

Paturin comprimé, Poa compressa, Blue grass, I should not mention, but some good works have lately adopted an old error of opinion about it, in supposing it to be the bird grass, which is extolled as forage, but about which it is almost impossible to get any correct information. I have made many attempts to obtain this bird grass, and to learn precisely what it is, and the result has been to satisfy me that, if a plant ever was cultivated in Virginia under that name, that plant was not the *Paturin comprimé*, which is a small grass that grows about walls, and in very dry places, the sparse leaves and stalks of which do not at all comport with the abundance and permanence of the verdure which is attributed to the bird grass. From the imperfect description that I have received of this grass I conclude that it is an *Agrostis*, and the similarity of name induces me to believe that it is the same with the *herds-grass*, which also is an American plant.

Paturin des bois, Poa memoralis seu angustifolia. In the experiments that I have made for several years with many different kinds of grass, the *Poa des bois* has always shown with advantage. It is rather the earliest of grasses (at least of those which are cultivated) to develope its leaves in the spring. Annually in March, it presents a mass of new and vigorous verdure, whilst the sap of the most of the other species of grass has not commenced to rise. Although the leaves are short, yet they are so numerous and so nutritious that they afford a very good mowing, even on sandy and indifferent soils. The hay which it gives, in respect to its fineness, its softness, and its verdure, excels that which is obtained from almost all of the other varieties of grass. The Paturin des bois is in other respects homely, durable, and not hard to suit with a proper soil, provided it is dry and sound, for I have never found it in low and humid meadows. A remarkable peculiarity which this grass possesses is that it grows voluntarily in the woods, and will maintain itself very well in the shade of the undergrowth. It grows also with much vigor on open lands, and even on walls, where it is often found, which proves it to be of uncommon strength of constitution. Notwithstanding these good qualities, the Paturin des bois has one most serious defect, that of not covering the ground well; its shoots, although numerous, grow always perpendicularly, and do not spread over the ground as those of many other grasses, but particularly the ray grass. Despite this objection, I regard it as one of the best of our indigenous grasses, either for early pasturage, or for sowing in meadows which it is intended shall be composed of the best and most superior plants. I have also found it very well adapted to afford verdure in the thickly shaded portions of pleasure grounds, where it will thrive for many years, whilst the ray grass and other turf grasses will quickly perish. Some forty pounds of seed per hectare are requisite.

Phalaris roseau, Phalaris arundinacea. Although this plant bears the appearance of a reed, it is very different in its qualities. Its leaves, cut when young, are tender, well stored with nutriment, and furnish excellent food for cattle. The *Phalaris* grows originally only on aquatic or very humid soils, but the following example will show that it will succeed in soils of a totally different nature. Mons. Jacquement Bonnefond of Annonay, a most worthy and intelligent farmer, has described to me a plantation of the Phalaris, which he has made with complete success on a very dry and gravelly hill-side, where verdure was never before seen. He obtained in this situation with this plant, not only vegetation, but two or three small mowings of hay, which the cows ate most heartily. This experiment was made with the variety called the *petit roseau panaché*, which is cultivated in some gardens as an ornamental plant. It has been repeated with the ordinary variety with success, by Mons. Descolombier of Moulins, whose farming is ever open to useful experiments. I, also, have some of the Phalaris, which is pretty well taken in very poor chalk land, where it resisted the drought of 1832. The discovery of Mons. Jacquement might bring about interesting results in farming.

Vulpin de prés, Alopecurus pratensis, Foxtail. Almost all observers in France, in England, and in Germany, who have studied meadow grasses, agree in regarding the *Vulpin* as one of the most precious of all, on account of its precocity, and the abundance of its forage. In the crops that I have

made for the grain, I have become acquainted with its qualities, and no grass better deserves to be brought into culture. The Vulpin loves humidity. In former editions of this work I have said that it could not be cultivated with other grasses, on account of its precocity. Later observations have caused me to change my opinion on this subject. Although the head is ripe much sooner than the other grasses, yet its vegetation continues, and a long reproduction of leaves renders it green and succulent, when the ray grass, and other good varieties, are ready for the sickle. It may be sown early in the autumn, or in the spring. About forty pounds of seed per hectare are necessary.

CURE OF MANGE IN DOGS.

To the Editor of the Farmers' Register.

In the last "Southern Planter," a writer gives us a remedy for the mange in dogs. Although in common life things which are considered valueless are compared to a dog, yet the fidelity and affection of that valuable domestic animal have always made him an object of gratitude and care with man. If we should disregard his comforts, or neglect to alleviate his maladies, we should be wanting in those noble qualities in which he has set us the example.

Some years ago, when residing in the upper country, I had a very beautiful and favorite pointer. He became mangy over his whole body, and very much reduced, so that I expected to lose him. I had a friend residing in the neighborhood who owned a tan-yard. He was kind enough to take my dog for a week or ten days, and dip him in the tan-vat several times each day. He was then rubbed well with a mixture of tanner's oil and tar, and sent home. In the course of a short time the scales began to peel off, and new hair to grow out. He soon became the sleekest and prettiest animal I ever saw, and was never again affected with the disease, or even visited by vermin for a year or two. I often thought, by his playful antics, that he was conscious of his obligations, and wished to express with kindness a gratitude which he felt; but the obligations were transferred to me, for he lived to afford me many an hour of sport and many a nice dish of game.

The disease is evidently infectious, and those that are subjects of it should not be permitted to consort with those that are not.

I hope the few brief remarks above, may lead to the relief of many a valuable animal for the mutual protection and enjoyment of himself and owner. W. J. DUPUY.

P. S. In the case above related, I first resorted to the usual remedies, such as sulphur, &c., without effect.

For the Farmers' Register,

EXPERIMENT OF FATTENING HOGS.

Surry county, January 1, 1842.

For the benefit of those persons who are giving twenty and thirty dollars a pair for *genuine* Berkshire pigs, I will give the result of an experiment made on feeding a lot of half Berkshires. These hogs were a cross of the Berkshire hog and the China, than which no hog, in my opinion, will yield more meat proportional to the quantity of food consumed. I must confess that I was somewhat disappointed with the result, as the pork cost me a good deal more than I expected it to do; nevertheless, I will give a detail of the trial, and let every one judge for himself.

On the 24th October, 1840, a lot of half Berkshire pigs, just eight weeks old, was separated from other hogs when fed, but suffered to run at large in a standing pasture, which was bad enough, producing little else than broom straw and poverty grass. The corn was ground into hominy, and measured out to them daily; and they were fed in this way until the latter part of July, when for several weeks, nearly two months, I put them on half rations, as they were allowed as much apple pomace during that time as they would eat. A few squashes and pumpkins, &c., were also given them in the summer and fall. And on the 30th of November they were slaughtered, being then just fifteen months and five days old. On the following day they were weighed, and averaged 374 pounds, which, at 4 cents, (the price Kentucky pork sold for in this county this winter,) amounts to $14.96. They ate 37 bushels 1½ peck of corn each, at 60 cents per bushel = $22.42½. So it will be perceived that I sustained a loss of $7.46½ on each hog. This startled me, and it was some time before I could convince myself that there was no error in the calculation; but it was fact; there could not be a shadow of doubt about it.

Hogs can be and are raised much cheaper than those mentioned above, but under dissimilar circumstances. If a farmer provide good clover for his hogs to graze, they will consume scarcely half as much grain; or if he be surrounded by a forest of oaks, they are easily and cheaply kept on mast, and perhaps this is the cheapest way hogs can be raised in eastern Virginia.

From the foregoing experiment I am well satisfied that, so long as pork can be bought for $4 per hundred, and corn sold for 60 cents per bushel, neither the Berkshire nor any other hog can be raised with profit, when corn is to form the principal article of food. It matters not whether it be given in the form of swill, be steamed, or baked into bread, it will vary in cost but little, and ultimately prove a sinking business.

BOLLING JONES.

FOURTH REPORT OF THE AGRICULTURAL SURVEY OF MASSACHUSETTS, BY THE REV. HENRY COLMAN.

We have had the gratification of receiving, from the author, the volume under the above title which has just been published, from which we shall make sundry extracts for the present number. The report is a new evidence of the zeal and ability of the Agricultural Surveyor of Massachusetts, and of the utility of the survey. Nevertheless, we find that it is the last report that is to be expected; the legislature, in a paroxysm of "pen-

ny-wise and pound-foolish" economy, having cut short the survey, and surrendered the honorable distinction before enjoyed by the commonwealth of Massachusetts, of being the only state of the union that had established so excellent a means of promoting agricultural improvement.

Mr. Colman has been invited to take charge of the 'New Genesee Farmer,' and will conduct its editorial department.

GRASS AND HAY IN FRANKLIN COUNTY, MASSACHUSETTS.

From the Fourth Report of the Agriculture of Massachusetts. Counties of Franklin and Middlesex. By Henry Colman, Commissioner for the Agricultural Survey of the State.

Grasses.—Grass may be considered as the principal crop. In the hill towns, and what may be called the uplands, the artificial grasses are cultivated, such as clover, (*trifolium pratense.*) herds-grass or timothy, (*phleum pratense,*) and red-top, (*agrostis vulgaris.*) In general, three pecks of red-top, one of herds-grass, and four to six pounds of clover-seed are sown, when land, which has been cultivated, is laid down to grass. The land is laid down with some grain, either wheat, rye or oats; and the grass-seed is sown with the grain. Barley is scarcely grown at all in the country.

The clover predominates the first year; the herds-grass the second. The clover is nearly extinct at the end of the second year; and the red-top, intermixed with various natural grasses, which spring up spontaneously, furnishes a permanent matting to the soil. In general, not nearly enough seed, particularly of herds-grass, is sown. The consequence is, that the product is very coarse the first and second year, which it would not be, if treble the quantity of seed were sown. Several farmers in the state, whose authority is entitled to respect, practise a much more liberal mode of sowing; and find an advantage in doing it in the improved quality of the hay. The average yield the first year is from two to three tons; the second it may be estimated at two tons; and for a continuance of three years after that, in favorable seasons and locations, it may be rated at one to one and a quarter ton per year. These lands in general, are mowed once only in a season. There is an instance in Conway, of a piece of moist land lying at the side and foot of a hill, where the soil is deep, being a rich mould, resting upon a substratum inclined to clay, on which, by copious top-dressings of barn manure, the product has been kept up, and averages yearly nearly three tons to the acre. Of peat lands, I know of no considerable tracts in the county; and, as yet, no great attention has been paid to the draining, either by open or under-ground drains, of wet lands. The quantity of this kind of lands is not considerable; but such improvements, where required, would be amply compensated.

The next quality of grass lands are the alluvions on the Deerfield and the Connecticut rivers, and small patches on their tributary streams. The alluvial lands on the Connecticut are rarely over-flowed, excepting at the breaking up of winter; and they are, therefore subjected to a course of cultivation the same as other arable lands. The rotation on these lands is commonly the first year corn, or potatoes with manure; the same the second year, and the third year oats, pease and oats, rye or wheat, with grass. Where broom corn is planted, it generally follows a crop of Indian corn; and is continued often two or more years on the same land. The annual deposites made upon these lands by the flood are not of great advantage, and the fertility of the soil can by no means be kept up without manure.

The low alluvial lands on the Deerfield meadows, essentially differ from these from a circumstance already alluded to. The waters on the low Deerfield meadows are set back from the great river, and remain comparatively quiet; and in addition to this, the banks and hills bordering the Deerfield and its tributaries are more steep in general than those on the Connecticut. Much more enriching matter is thus brought down from them to the river in times of rain and freshets. These lands, therefore, annually and commonly oftener over-flowed, constituting the lowest meadows on the Deerfield river, are never ploughed. They require no manure; and being entirely alluvial and receiving the richest deposites, are of extraordinary and inexhaustible fertility. These meadows are always mowed twice; in some cases, three times; and the annual yield is generally estimated at three tons to the acre. The hay on these meadows is of a very fine quality, known there familiarly as the English bent (*agrostis alba*). It is a natural grass, and forms a fine and impervious sward.

The upland intervales on the Deerfield, are devoted to cultivation; and most of this land is seldom suffered to rest. For hay, the main dependence is upon the low flooded meadows; and those low and uneven portions, which it is difficult to reach with the plough.

An example has been given to me of the product of one of these low meadows in Deerfield containing nine acres, at a place called Old Fort.

The first crop of hay was, - -	25,325 lbs.
" second crop, - - -	15,120
	40,445 lbs.
The hay was sold and delivered as soon as cured, at nine dollars per ton,	$182 00
The fall feed, sold for - - -	4 50
	$186 50
The whole labor was performed by contract at four dollars per acre for both crops, - - - - -	36 00
Leaving a balance in favor of the land of - - - - - - - -	$150 50

The hay was considered as sold at a low rate. The same quality of hay in the following winter brought 13 dollars per ton.

The land has been estimated at one hundred dollars per acre. No manure has been put upon the ground. The produce in this case, was not more than an average crop. This yield was at the rate of 4,494 lbs. to the acre. First crop, 2,813 8-9 per acre; second crop, 1,657 7-9 lbs. per acre. This constitutes some of the best land in the meadows. There is that, however, which is deemed even more productive.

The hay from these natural meadows is exceedingly coveted by the cattle and remarkably nutritious. It consists of a very great variety of plants, but what is called the English bent (*agrostis alba*,) prevails with a slight intermixture of clover. I do not know what has given it the name of English, as it is without doubt indigenous to the soil. It requires to be cut early, otherwise it becomes hard and wiry. Some of the farmers are in the habit of making or drying this hay much less than formerly. It was considered best to dry it as much as possible; but this is not now the case. Hay, wet from external moisture, whether dew or rain, always suffers and becomes mouldy and sour, if packed away with any of this dampness upon it. But hay when perfectly dry may be put away with much of the sap remaining in it; and though it sweats severely in the mow and becomes somewhat discolored from the heat, yet it is not the less relished by, nor the less nutritious to, the fatting cattle. This is the actual experience of some of the best feeders; but though no evil may come from giving such hay to cattle soon to pass into the hands of the butcher yet in the condition in which it is often given to fatting cattle, it would be quite pernicious to horses. There is reason to believe, that hay is generally too much dried; and with some farmers, the practice of curing it in the cock is much approved. In this case, the hay being perfectly dry from any external wet, after being slightly wilted in the sun, is made up into cocks. The second day these cocks are opened and afterwards doubled. In good weather it will soon become sufficiently cured to be carried safely into the barn. In bad weather it is in a great degree secure from the effects of rain, if the cocks are made up with care. In this way, the hay is never so much dried as to be broken; nor are the leaves and seeds, as in the common way of making hay by tossing it about a great deal, scattered and lost. Two of the best farmers in the county, residing in Bernardston, are of opinion, that herds-grass should not be cut until it is ripe, and the seed perfectly formed. They speak with confidence in this matter from having made many experiments in the fatting of cattle. They are persons, whose word is above question and whose judgment is entitled to great respect.

ON THE QUESTION OF TOPPING AND STRIPPING CORN. HARVESTING THE CROP.

From the same.

The subject of topping the stalks has been much discussed; and its inexpediency may be considered as settled. A Pennsylvania farmer, highly intelligent and observing, made an experiment with a view accurately to test this point. Taking three equal rows in the same field, topping two and leaving one untopped, the result was as follows:—

"Produce of the row which had not been topped, nine bushels and five-eighths of corn in the ear.

"One of the rows which had been topped and stripped,—that is, the blades of the plant taken off,—measured seven bushels and six-eighths; and the other, topped and stripped, measured seven bushels and three-eighths of corn in the ear. Thus it clearly appears that mutilating the corn plant before its fruit is perfected, is a very injurious practice."

The experiment of Josiah Quincy, of Quincy, Norfolk county, was to the same effect. This was upon carrots, and I shall give the account in his own words:—

"It was stated confidently, by some English writer on the cultivation of carrots, that the tops might be cut early for the purpose of feeding cattle which were soiled, not only without injury, but even with benefit, to the roots, which it was said, would in this way grow larger. Mr. Quincy took twenty-six beds of carrots in the same field and of the same size, with a view of fully testing these statements; and in the month of July, when the lower leaves first began to wither, he caused every other bed to be cut as directed, being careful not to crop the crown or the head of the root—so that there was a cut to an uncut bed alternately through the whole piece. They were gathered, and the roots measured carefully, on the 20th October. The total product of the uncut beds was 104½ bushels: the total product of the cut beds was 58 bushels. Judging by the eye, the size of the roots of the cut bed was nearly two thirds less than that of the uncut bed."

But the question may be considered as put to rest by the experiment of William Clark, Jun., of Northampton, Hampshire county. The experiment was conducted with much care and intelligence; and, omitting several of the details, I shall give only the results:—

Row No. 2, on which the experiment was commenced, was as follows, viz:

46 hills on which the stalks had not been cut, gave - - -	42 lbs. 8 oz.
Dry shelled corn, equal per acre to	bs. 60, 8 lbs.
46 hills from which the stalks had been cut, gave - - -	33 lbs. 7 oz.
Dry shelled corn equal per acre to	bs. 47, 18 lbs.
The loss by cutting the stalks per acre was - - - - -	12 bs. 46 lbs.

The four rows taken together, stand as follows:

No. 1 and 4, on which no stalks were cut, gave an average per acre of 60 bs. 8 lbs.

No. 2 and 3, from which half the stalks were cut gave an average per acre of 54 bs. 25½ lbs.

Loss by cutting half the stalks per acre, - - - - - - 5 bs. 38½ lbs, or cutting all the stalks would make a loss equal per acre to - - 11 bs. 21 lbs.

The difference in the result of the two cases is 1 bs. 25 lbs. per acre; or in the two experiments, if it may be so termed, there is an average loss by cutting the stalks, of 12 bs. 3½ lbs. per acre; a loss quite equal to all the expense of hoeing and harvesting. Mr. Clark adds, "if this experiment is a fair test, it seems that about twenty per cent. or one-fifth part of the crop is destroyed by cutting the stalks in the way they are usually cut." Another exact farmer in Conway has made a similar experiment in reference to this very point. By a careful measurement he states that the difference between cutting the stalks at the customary time or leaving them uncut until after the corn is ripened was eight bushels per acre in favor of the latter practice.

Mr. Clark advances another opinion, which is

quite conformable to my own and to the experience of many other farmers. "This twenty per cent. is not saved at the expense of losing the stalks; they are worth as much, and I think more, all things considered, after the corn is harvested, than they are when gathered in the usual way. If, after being bunched up in a green state, they heat or become mouldy, (a case of frequent occurrence,) they are utterly worthless, except it be for manure; I know of no animal that will eat them. But after they have once been dried by the sun and wind, a subsequent moderate degree of mouldiness, seems to be no injury." This conforms to the opinion of one of the best farmers in Northfield, Franklin county, who is in the habit of gathering his corn and then cutting up the stalk at the ground.

The mode of harvesting Indian corn is of considerable importance. On this subject the opinions of farmers are at variance. Some choose to top the stalks as soon as the corn is glazed, and gather the corn after it has become fully ripened. Others prefer leaving the whole until the grain is sufficiently ripened to be cribbed, then gathering the corn, husking it as it is gathered, and collecting the fodder afterwards. Others choose as soon as the corn is glazed, or is so far advanced that an ear fit for roasting is not to be found in the field, to cut the whole up at the ground and shock it in the field for ripening. This practice, is almost universal in New York, but it prevails only partially in Franklin county, where in general the first described mode of harvesting is adopted. In many places the but-stalks after the corn is gathered, are left in the field to be browsed by cattle, a management which is wasteful, and has nothing to recommend it.

I shall take the liberty in this matter to detail my own experience, while a resident in this county. The leaving the corn untopped until it is sufficiently advanced for gathering, and then cutting it up at bottom, allowing it to finish the ripening in the shock, has sometimes with me been attended with success. In some cases, however, I have had by this management so much mouldy and soft corn as to question its expediency. But as I think I have discovered the causes of my failure, this method now commends itself strongly to my judgment.

The summer of 1832 was so cold, that corn generally was three weeks behind its usual condition; and fears were entertained that the crop would be entirely cut off. On the 9th of September there was a slight, and on the 12th and 13th, there were severe frosts. Corn was generally in the milk; and, in many places, much was killed. The fogs on the river near my residence served as a protection to my crop. Under these threatening appearances, fearing through delay the loss of my whole crop, I determined to cut up the whole at the ground as soon as it should be slightly glazed; and the results and facts in relation to it, I took pains to record.

I was desirous to ascertain whether corn cut in the milk and not at all glazed, would ripen. Three stalks with one ear on each were cut in this condition and placed in as favorable a situation as possible for the access of the sun and air. They ripened perfectly; and to appearance became as fair and hard and heavy as any; but the experiment on a whole field could not be advised, as so favorable a situation for curing a large quantity could seldom be obtained. I began cutting my corn on the 14th September, after having previously cut out the suckers and barren stalks. In the field which I took first, the corn appeared dead; but this was occasioned by the rust, not by the frosts. This corn being cut at the bottom and not suffered to be laid upon the ground, several hills were brought together, the stalks were spread widely at the bottom, and were tied by a single band at the top. Much of this corn upon husking, appeared of a pale yellow, and a good deal of it was soft and mouldy. The shocks did not stand firmly, and many were over-turned by the wind. The centre hill, around which the stalks were gathered, should not have been cut until the time of husking, but should have been left as a support to the shock. Another field where the corn was slightly glazed and the stalks very green, was cut, tied in small bundles above the ears and put in small shocks or stooks. This came out better than the former, but not so well as could be desired. It was cut too early, and was not suffered to remain long enough in the shock.

Two other fields were necessarily left to a later period after the corn had become fully glazed, that is in the main every kernel on an ear was well touched, though the stalks were still green and succulent. It was tied near the top in small bundles; put up in small shocks, and spread at bottom so as to give free access to the air. This corn at husking came out bright and sound, with less refuse than ordinary; and the fodder was succulent and of the best quality.

There is a small matter connected with this subject to which my attention was directed by an excellent farmer in the county. His advice was by no means to shock the corn, thus cut up and gathered, upon grass ground, as is often done on the borders of the field, because the grass is likely to exclude the air from the bottom of the shocks. Upon the whole my own judgment, especially liable as we are to early frosts, is to cut up and shock the corn as above described as soon as it is well glazed; and it is a safe error to do it too early rather than too late. The fodder in such case is always of superior quality.

RELATIVE MERITS OF BERKSHIRES AND WOBURNS—BANTER FROM MR. MAHARD TO DR. MARTIN.

From the Kentucky Farmer.

The reader will find below a letter written by Mr. Mahard upon the relative merits of Woburns and Berkshires. We have admitted it on the ground that it discusses facts interesting to the breeding public in relation to two popular breeds of swine and particularly as it proposes a test of their comparative merits in a way more satisfactory than any hitherto tried. At the same time, however, we regret to perceive that Mr. M. has adopted a style of discussion calculated to provoke a controversy likely to degenerate into personality. Although individually sick and tired of mere paper discussions on the question, which is the best breed of hogs, we do not feel at liberty to decline discussions which may lead to the discovery of

truths useful to the pork raisers of the country. Yet we dare say that, if we were to exercise our right of either returning the communications of gentlemen or of expurgating their personal and offensive expressions, they would get into a higher passion on account of the act than they exhibit in their productions. There is an exceeding degree of sensibility manifested by breeders whenever a discussion of the merits of this or that breed of animals is in hand. As much heat is exhibited, by the advocates of the various breeds, towards each other, as is usually observed between the different political parties. We shall take no side in these controversies. Throwing our pages open alike to all, we have only to say to each, bring forward your strongest facts and give our readers the benefit of them. * * * —*Ed. Ky. Far.*

Cincinnati, 2nd Dec., 1841.

To the Editor of the Kentucky Farmer:—I find on looking over various agricultural papers of the United States, that Dr. S. D. Martin of Kentucky, has published a trial made by himself and James F. Taylor, of feeding a Berkshire sow and two Woburns, for ten days, and as the whole particulars of the case have not been published by the Doctor, I feel anxious that they should be, for the information of all concerned, and as he is such a stickler for *facts*, he of course will have no objections to what I am about to state.

What I learned of this trial of feeding between Doctor Martin and Mr. Taylor, was at the Doctor's own house last September, when I visited him in company with Mr. Affleck, editor of the Farmer and Gardener. Here I met Mr. James F. Taylor, and heard him and Dr. M. discuss the whole subject, and I must confess, after which, I could not but wonder that the Doctor had come out in the public prints and published this trial, as I think it can be made to appear from all the facts in the case, that he has gained nothing by it, only so far as it helps to make a noise about his hogs, and keep them before the public.

It appears on the 13th August last, Mr. Taylor placed a Berkshire sow of his, and Dr. Martin two Woburn sows, in the hands of a Mr. Weathers, a disinterested man, to be fed for ten days, on 5 pounds of corn per day. Mr. Taylor is a nephew of the Doctor, and Mr. Weathers is a tenant. These things I state because they are facts. Well, as to the result, Doctor M. and Mr. T. agreed as to the gain of the Berkshire sow and one of the Woburns, which they said was 21 pounds each on fifty-two pounds of corn in ten days, but upon that of the other Woburn sow, Courtney, on the same allowance and same number of days they disagreed. Doctor, M. asserting that she had gained 30 lbs., while Mr. Taylor contended that she was incorrectly weighed, and that he did not believe that she had made any such gain. I now contend that Doctor M. has published to the world what is not a fact, for it is disputed by his own nephew, Mr. T., that the Woburn sow, Courtney, did gain as much as was represented she did.

The Doctor goes on to state, from this trial made with Mr. Taylor, that it is a fact that the Berkshire hog is a greater consumer than the Woburn. (See his communication particularly to the Tennessee Agriculturist, November No. p. 259.) Now only hear what he told me in a private conversation on this very subject. He said that on the day he brought home his Woburn sows from Mr. Weather's, he told his man Patrick to put up Courtney and give her as much as she would eat for two days, and then they would weigh her again. He did so, and found she eat a bucket of swill! a bucket full of apples! and nineteen ears of corn! and gained 19 lbs., and from these facts, the Doctor concluded that the Berkshires were the greatest consumers! The gain of 19 lbs. in the two days was principally in the weight of food given her, and with which she had gorged herself, and I believe just as much in it, admitting that the Doctor was correct, as I do in an animal gaining 30 lbs. of *flesh* on 51 lbs. of corn. Such a thing is utterly impossible, and if she did weigh 30 lbs. more at the end of the ten days, it was because her stomach was full of water, or something else besides the 51 lbs. corn consumed.

It will now be seen, that the trial between Messrs. Martin and Taylor proves nothing at all to me, regarding the relative merits of the different breeds of swine, and inasmuch as the Doctor has been bragging and bantering the whole world to feed against his Woburns, and as I do not believe that there has ever been a fair test yet made, I propose selecting six of my Berkshire pigs, 3 months old, and I call upon Dr. M. to select the same number of his Woburns, and put them into the hands of a disinterested man together, to be fed from twelve to fifteen months in the usual method of feeding hogs for pork—to pasture them in the summer, and to have all the grain measured that they consume, and then let them be drove to this market or to any other that may be agreed upon, and the hogs weighed alive, then killed and weighed again, and the whole trial be published to the world.

I am now busy in packing pork in Covington, Kentucky, and I wish to mention a *fact* with regard to a lot of 103 head of hogs, 69 of which were *one-half* and *three-quarters* Berkshire, belonging to N. McNeese, of Harrison county, Kentucky, the whole averaged 268 lbs., gross at home, and after being driven 50 miles to this place, and kept on hand for several days, they were slaughtered and weighed 219 lbs. net. The usual loss between gross and net lots, in common hogs, is one fourth and over, this shows a gain of 18 lbs. per head in this lot; and had the Berkshire cross been weighed by themselves, it would have been still greater. I do not think their loss between gross and net weight would have been over 40 lbs. a hog, or less than one-sixth.

So thoroughly am I convinced in my own mind that the Berkshire hog is superior to all others, that I am anxious to have a fair and impartial test made between them and any other breed, and the sooner it is done the better. As far as I have been able to learn from those to whom I have sold Berkshire pigs, none have been disappointed in them. A correspondent of mine writes from Tuscumbia, Alabama, under date of 19th November last, informing me that a lot of Berkshire pigs I had sent him had arrived safely. He said he had an opportunity of seeing one or two pairs of Doctor Martin's thorough-bred Woburns. "There is," says he, "humbuggery in the Doctor, his hogs *won't do what he says they will.*"

"They are a large boned, coarse hog, and not a good shape, and as to their being sustained on less food than any other breed of hogs is out of the question, his experiments to the contrary notwithstanding. To say that a large boned, coarse haired hog, that will not mature short of 3 years, and weighing from 8 to 1200 pounds, can be sustained on the same amount of food that a neat boned, muscular, compact hog, that will mature in from 12 to 20 months, is contrary to nature and philosophy, and any individual instance to the contrary only proves an exception to a "general rule." He further remarks, "that the Doctor states in a letter to a friend of mine, that he has not ascertained at what age his Woburns would mature, as he has never fed any long enough, though he has fatted some over three years old!!"

Those papers that have copied Dr. Martin's trial of the Woburns and the Berkshires will, as an act of justice, please do the same with the above. Most respectfully,

JOHN MAHARD, Jr.

[We have given place to the foregoing article, not because we approve its *manner*, or take sides with the writer, but because we had published the previous article commented on. It is unfortunately the fact that there is a great deal of humbug in every branch of stock-breeding and selling, by which the salesman can derive large profits from exaggeration and deception. Without meaning to detract from the real merits of either the Woburn hogs, of which we know nothing practically, or of the Berkshire hogs, of which we know something, and think favorably, we are well satisfied that there is much more of humbug than of truth in the high-colored recommendations of both, and especially of the latter, because best known to us; and that of the numerous communications published in commendation, much the greater number are merely elaborately constructed and carefully disguised breeders' and salesmen's advertisements and puffs. Of course, this and every one of many such expressions of our opinion, is calculated to injure our interests with the most active and influential writers for and supporters of agricultural periodicals, who are (unfortunately) the producers and sellers of humbugs, in some one or other department of agriculture. And not only do we thus lose the favor and incur the hostility of the whole humbugging class, but fail thereby in pleasing their victims, or agricultural readers in general, who are much better satisfied (at the time) when cheated, than to be warned of and guarded against deception. Even when deriving no *direct* gain or reward from aiding the system, it is greatly to the pecuniary interest of an agricultural editor to act as if guided by the motto. "Humbug for ever!" and to lend his publication entirely to such service, so far as demanded.—ED. F. R.]

From the (Nashville) Agriculturist.

POTATOES, GAPES IN CHICKENS, TETTER, MOSQUITOES.

To Dr. J. Shelby—dear sir—Agreeably to your request, I send you the root part of a corn stalk, raised in the following way. I dug a trench about 20 inches deep. One object was to try an experiment with potatoes, to see if they would thrive well at a considerable distance beneath the surface. I planted my potatoes with a few grains of corn at the bottom, covered with chip manure, mixed with the soil, and after they came up, I filled the trench as fast as I could without smothering them. I at the same time planted two grains of corn on the surface near by, one of which I cultivated by hoeing about it and making a hill, and to the other I made no hill, nor loosened the soil near it. The season was a very dry one, with but little wind when the corn was in blossom. When it was ripe, I found a good well set ear on the stalk, I did not cultivate, further than to scrape away the weeds and grass. None of the others produced as well, which I supposed might be accidental. I hilled up the trench so as to make it about two feet from the bottom. The next spring I dug my potatoes and found a very poor yield, though I found potatoes at all depths. I have since tried the same experiment in potatoes in a good season, and with nearly the same success. I was induced to try the experiment from one I had tried before. I took sprouts from potatoes and planted them in hills in my garden, and cultivated them as usual. In the fall I dug them, and their yield was moderate. I overlooked one hill which came up the next spring, and as they were of the late kind, I knew they would produce but little under the common mode of cultivation, and continued to hill them up to within about six inches of their top until fall. When I dug them up I found about a dozen very large good potatoes, and but one too small for cooking. I suppose it is known that the late kind of Irish potatoes, if planted early in this climate, hardly yield the amount planted. The best time to plant is from 25th of June to 1st August. I suppose it is likewise known that the growth of potatoes can be protracted by hilling them up. Hill up potatoes that are in blossom, and the blossoms will fall off. A new growth commences, and in time they will blossom anew. In this way one can put off the ripening of early planted potatoes till fall.

There is in this climate a difficulty in keeping potatoes from deteriorating in quality. They will keep in some parts of France by burying them 3½ feet beneath the surface. I have tried them here 5 feet, and still they were within atmospheric influence. I once found a small piece of sweet potato, perfectly sound, four feet beneath the surface, in what had been a potato cellar beneath my kitchen, which to my certain knowledge must have been there ten years, and I believe twenty. From thirty years' experience in this county I am convinced that the surest way to raise the largest and best Irish potatoes with the least trouble is to have them so near the surface that the ground will crack as they expand. I am not certain but the same may be true in sweet potatoes. * *

I have seen in the Farmers' Register, as taken from the Cultivator, two communications upon gapes in chickens. Their authors appear not to

understand the cause or best mode of cure, both of which are very simple. One recommends as a preventive, the taking of the chickens early from the hens and "scanting them in their food." A fine way, indeed, for having fat chickens for the table! The French mode of starvation for the cure of disease is founded in philosophy, but a deeper philosophy rejects it altogether.

It has been a long time observed that when a person settles a new place, it will be a year or two after he gets a hen-house before there will be gapes among his chickens. I believe those who have no hen-house or covered place for hens to roost or set in, are never troubled by the gapes. Some have two hen houses, keeping one uncovered alternately through the year, and so avoid the gapes. If you will examine a hen coming off with chickens that will have the gapes, you will find her abounding in lice, which will be communicated to her chickens. Should you take these chickens previously, and keep them from being lousy, they will not have the gapes, and there will be no necessity for "scanting their food." It is possible that chickens already having the gapes may have life protracted and perhaps get well by "scanting their food," on the principle practised with patients, whose vitality is nearly extinct. Lice are continually sucking the blood of their victims. If you will cut open and examine a chicken having the gapes, you will find one or more long worms in its windpipe, obstructing its breathing. These sometimes can be thrown out by taking the chicken with its head from you, raising it up at arms length, and bringing it down very quick.

If you will examine the blood of a gaping chicken, you will find it pale and thin; a sure sign that it lacks iron. Under this belief more than twenty years ago, and after having tried every known remedy to no purpose, I concluded to try iron. I take rusty nails, iron turnings or filings, put them into an unstopped bottle with good vinegar, and set it in the sun, often shaking it till it becomes black. I put a table-spoonful of this into the dough, which I feed, and with it cure or prevent the gapes. I once gave it to a sick hen, that was pale and so weak that she could neither walk nor stand without falling forward or back, and in a few days she was well, and afterwards raised six or more broods of chickens. Was not this disorder the pip?

I published the remedy eight or ten years ago, and was informed that a certain gentleman, once somewhat noted as a lawyer, and since as a preacher, used it and said it killed every creature that ate it. He must have got iron filings mixed with brass, which is common in most mechanics' shops. I have constantly used it, when needful, and have never know any harm from it. I have a hen-house, but my hens roost on the trees near the house, and although I have seldom less than thirty, and often more, and raise chickens, I have not had an instance of gapes for several years. A setting hen or other fowl is said to have fever, because their heat is greater than at any other time; but it is not fever. It lacks every characteristic of fever, but increased heat. * *

Farmers and laboring men, as well as others, often suffer from tetter, a disorder, which is often attempted to be cured, and not always with success. The fee for trying to cure, and I suppose commonly with aquafortis, is said to be sometimes $10. Perhaps a dozen years ago, I often had an itching humor on the backs and sides of my fingers, which was quite troublesome. In two or three weeks numerous small pimples would arise, containing a fluid, which I would let out with a sharp pointed knife. Then they would heal and disappear for some weeks, when they would come on again in the same way. After two or three years the humor appeared to quit the fingers and come into the palms of my hands. They would at first itch, and then in places appear as if scorched, and then the skin would crack. I soon learned it was tetter, for I had known nothing of the disorder. On inquiry I found it was seldom cured, and having no ten dollars to give as a fee, I determined to search for a remedy until I found one. I believed that vegetables contained an antidote for all disorders, and sought a remedy among them. I tried various things for three years or more before I found one. One day, walking in my garden and passing some rue, I recollected having heard that if a person handled rue, when the dew was on, it would blister. I took some leaves and rubbed them in my hand, and instantly the itching ceased. I pounded some and added water to it; and rubbed it on my hands frequently, and in about three weeks the tetter entirely disappeared. But it shortly broke out again, and I cured it again. This convinced me it was a humor pervading the system. After a while it appeared only in the spring and fall, and so continued to do for two or three years, when it ceased altogether for several years, and I supposed I was free from it, until a few weeks ago, when it came on as bad as ever; but I soon cleared it out. You undoubtedly have heard that "rue and rum" was once a catholicon. Of course it can be used internally with safety. Those who wish to expel the tetter virus totally from their systems, can drink rue bitters. I have had no opportunity of trying rue on tetters except on the hands, but suppose it will be equally efficacious, wherever the disorder may be. I have only to caution all who use it externally, not to suffer the sun to shine long upon the parts wet with it, for several days; for sunshine will produce inflammation.

As it sometimes happens that children lose their lives by eating Jimson (stramonium datura) and as I did not know that any specific had been discovered against it, I a few years ago tried a sort of experiment with the view of finding one out. Passing a barrel, which had stood too or three days nearly full of rain water, I saw thousands of little wiggle-tailed animals. (A learned man would have called them embryon or chrysalis mosquitoes.) They darted to the bottom immediately; but soon rose with their mouths to the surface, to enjoy the warm sun and the air. I watched them several days, wishing to see them shuffle off their "mortal coil" into mosquitohood. A full grown one would rise with its back a little above the surface, and after a short time its shell would open at the top and expand into a complete boat. (Perhaps antiquarians trace keel boats to this origin.) Shortly a mosquito would raise itself on its tiny legs, and stand erect. After a little it expanded and dried its wings, and then flew and perched on the side of the barrel. Having sufficiently satisfied my curiosity with *Mosquitology*, I gathered a parcel of Jimson weed,

and cutting it up fine spread it thickly on the surface of the water. There were many interstices between the pieces, where shoals of the little merry fellows could enjoy their pleasant sunshine. In two or three days I found none near the surface. They kept at the bottom, where they could not come to maturity. I noticed this until I was satisfied that the poison at the surface prevented their rising. I then sprinkled a pound or more of slacked lime upon the top. A part fell to the bottom, and a part remained at the surface. Shortly my little pets rose to the top "as merry as crickets." A mosquito can hatch out only at the top; for they drown as easily as a fly.

Should any one about me become poisoned with Jamestown weed, I should give lime water as a specific. WILLIAM CHANDLER.

Mill Creek, near Nashville, Dec. 1841.

UNITED STATES AGRICULTURAL SOCIETY.

Constitution of the Society

The style of this society shall be, "*The Agricultural Society of the United States.*" Its objects shall be to improve the condition of American husbandry, and, from its central position to serve as a medium of communication and of action with other agricultural societies throughout the union.

Article 1. This society shall consist of such members as shall, at the formation of the same, sign the constitution, and pay to the treasurer two dollars, and one dollar annually thereafter as long as they shall continue members.

Art. 2. Any citizen of the United States may become a member of this society by paying the fees required for membership.

Art. 3. Any agricultural society in the United States shall become an auxiliary society, upon paying to the treasurer the sum of ten dollars, upon application, and five dollars annually thereafter; and each auxiliary society shall receive no less than five printed copies, of the annual proceedings of this society, and shall also be represented by such delegate or delegates as it may appoint to the annual meeting of this society, and on all questions to be decided by the society such delegation shall be entitled to ten votes.

Art. 4. Any person paying to the treasurer ten dollars shall receive a diploma of membership for life.

Art. 5. The officers of this society shall consist of one president, one vice president from each state and territory, and one from the district of Columbia, a recording secretary, a corresponding secretary, and treasurer, and a board of control, consisting of five members, three of whom shall constitute a quorum.

Art. 6. The president, and in his absence one of the vice presidents, shall preside at all meetings of the society. By the concurrence of the board of control he may call special meetings of the society, giving public notice thereof, by advertisement, at least three weeks before said meeting. He shall draw all drafts on the treasurer for moneys paid out, which drafts shall be countersigned by the recording secretary; and the treasurer shall, at the next annual meeting, make a full statement of all receipts and expenditures, setting forth as well the items as the amount thereof.

Art. 7. The vice presidents of the states of Virginia, Maryland, Pennsylvania, and Delaware, and of the district of Columbia, shall be ex officio members of the board of control, provided no act shall be done by said board without the presence of a quorum of the original board.

Art. 8. The recording secretary shall keep a full record of all the proceedings of the society, and supervise the publication of them as he may be directed.

Art. 9. The corresponding secretary may be one of the five members constituting the board of control, and in addition to conducting all the correspondence of the society, shall keep a record of all expenditures ordered by said board, and, in short, perform for said board all the purposes of a secretary, and shall receive such compensation therefor, as said board, with the consent of the president, may allow.

Art. 10. The board of control shall consist of five members, living in, or at a convenient distance from this city, who shall perform all the executive duties necessary to the purposes of the society not especially assigned to other officers. They shall avail themselves of all the means in their power to become acquainted with the agriculture of foreign countries, and through such aid as they may be able to receive from our diplomatic agent abroad, as well as our consuls, shall, if consistent with the pecuniary means of the society, introduce from abroad whatever they may think materially calculated to improve the agriculture of this country, whether it consists of information as to new and improved modes of culture, seeds, plants, additional articles of cultivation, agricultural implements, or domestic animals; the disposition of which shall be made at the first annual meeting of the society.

Art. 11. The board of control shall also use the necessary means of having a large exhibition, at each annual meeting, of improved agricultural implements and machinery, with full and public trials of the same; of improved stocks of all kinds, and particularly of inviting the exhibition of such animals as have taken premiums at other agricultural shows, with a view of testing the superiority of prize animals themselves; also of the different breeds of animals, for the purpose of comparing the advantages of each. They shall affix to such exhibitions such premiums as they shall adjudge suitable, appointing such judges as they may select to award the same, which judges shall not only assign their preferences, but shall draw up a detailed report of their several examinations; setting forth fully a description of the articles or animals adjudged, and the grounds upon which their preferences are awarded.

Art. 12. It shall further be the duty of the board of control, when they think it expedient, to procure a model of such implement and machinery as may have received a premium, to be kept in some suitable and convenient place, selected as an agricultural repertory, for the inspection of the public, and particularly of members of the society.

Art. 13. The said board may also award premiums for prize essays, to be read before the society, for well conducted and well reported experiments in agriculture, having reference in the

same to the pervailing agricultural productions of the different societies of the union.

Art. 14. The said board shall give due notice, by advertisement, of the time and place of such exhibition, the premiums to be awarded, and the committee by whom they are to be awarded; and for the expense attending the discharge of the duties herein imposed, they shall draw requisitions on the president, setting forth, severally, the items of expense, which requisitions shall be recorded by the recording secretary, and the president, if he approves the same, shall thereupon issue his draft on the treasurer for the amount.

Art. 15. The said board shall also be instructed to make efforts to obtain funds for the establishment of an agricultural school in the district of Columbia, and, appurtenant thereto, a course of public lectures on agriculture, chemistry, botany, mineralogy, geology, and entomology, as appropriate sciences to the great *business of agriculture*, and an experimental farm, which, with the buildings and improvements thereon, shall be set apart for ever "*as an establishment for the increase and diffusion of knowledge among men.*"

Art. 16. The board of control shall procure an appropriate seal for the society, to be attached to diplomas or other documents or instruments which may be issued to honorary members or other persons, under the direction of the society. They shall fill all vacancies that may occur by death, resignation or otherwise, either in their own body, or the list of the officers, to continue until the next general meeting.

Art. 17. In further aid of the purpose of this society, the said board shall invite some suitable person to establish an agricultural publication in this city, and shall also petition congress for the incorporation of this society.

Art. 18. The first general meeting of this society shall be in the city of Washington, on the first Wednesday in May next, and thereafter at such times as the society may direct.

Art. 19. All moneys paid to the treasurer, either for subscriptions or as donations to the society, shall be deposited to the society's credit in such bank or institutions as the board of control may direct, and can only be withdrawn upon the requisition of the president or acting president, countersigned by the secretary and treasurer.

Art. 20. This constitution shall be amended only by a vote of two thirds of all the members present at an annual meeting of the society; but the board of control may, by the aid of the president, establish any needful by-laws for the better order of the society not incompatible with this constitution—which by-laws may at any time be amended by a majority of the society present.

Art. 21. Elections for all officers of the society shall be held by ballot at every general meeting thereof; but, until an election at the general meeting in May next, the following persons shall be a committee to appoint the officers hereinbefore mentioned, and to make publication of the same, in ten days from this time:

The Hon. Levi Woodbury, of New Hampshire; Hon. Lewis F. Linn, of Missouri; Hon. Wm. C. Rives, of Virginia; Hon. Wm. Cost Johnson, of Maryland; Hon. Dixon H. Lewis, of Alabama; Hon. John Hastings, of Ohio; Hon. H. L. Ellsworth of the District of Columbia; Hon. John S. Skinner, of the District of Columbia; and John F. Callan, Esq. of the District of Columbia, were then appointed a committee to select the officers of the society provided for in the constitution, to serve until the regular election in May next.

—

The committee, appointed by the Agricultural Society of the United States to select the officers of the society to serve until the first general meeting and exhibition on the 4th day of May next, have met, and do hereby recommend and report the following gentlemen to fill the offices annexed to their respective names. The recording secretary is requested to publish the names, and give special information to each individual of his selection.

LEVI WOODBURY.
Chairman for the Committee.

President, James M. Garnett; *Corresponding Secretary*, John S. Skinner; *Recording Secretary*, John F. Callan; *Treasurer*, Edward Dyer.

Board of Control—Levi Woodbury, Elisha Whittlesey, Alexander Hunter, John A. Smith, W. J. Stone.

Vice Presidents—Maine. George Evans; New Hampshire, Isaac Hill; Massachusetts, B. F. French; Connecticut, Eli Ives; Rhode Island, Gov. Fenner; Vermont, Wm. Jarvis; New York, C. H. Bement, New Jersey, C. S. Green; Pennsylvania, George M. Keim; Delaware, J. W. Thompson; Maryland, Thomas Emory; Virginia, Edmund Ruffin; North Carolina, Edmund Deberry; South Carolina, Wade Hampton; Georgia, W. Lumpkin; Alabama, Dixon H. Lewis; Louisiana, Alexander Mouton; Arkansas, Archibald Yell; Tennessee, F. H. Gordon; Mississippi, M. W. Phillips; Kentucky, Chilton Allan; Missouri, Lewis F. Linn; Illinois, A. W. Snyder; Indiana, Solon Robinson; Michigan, Isaac E. Crary; Ohio, John Hastings; District of Columbia, H. L. Ellsworth; Florida, R. W. Williams; Iowa, Timothy Davis; Wisconsin, Henry Dodge.

The vice presidents of Virginia, Maryland, District of Columbia, Pennsylvania, and Delaware are ex-officio members of the board of control.

J. F. CALLAN, *Rec. Sec.*

[Though it is contrary to our usage to publish the constitutions and preparatory proceedings (of merely *intended* operations) of new agricultural societies, we have made an exception to that usage in favor of the "United States Agricultural Society," recently instituted at Washington—an exception due to the magnitude of the plan and object, and also to the public spirit and patriotic views of the individuals who have founded the society. But neither our high respect for the founders, (the principal of whom are also our valued friends,) nor the unexpected and unsought honor which the society awarded to us among their appointments to office, will prevent our again expressing the opinion and the fear that a society so constituted, and so located, cannot possibly *work right*, nor do much good in promoting agricultural improvement, compared to the results that might be produced from the operation of as much talent, zeal, labor and money, di-

rected differently. It cannot be expected that any considerable number of individuals, or enough to maintain the semblance of a "United States Agricultural Society," can be induced to travel to Washington, from all the states of the union. And even if such incredible sacrifices were made, and some members were to attend from Maine, Iowa, Missouri, Louisiana and Florida, as well as from the near neighborhood of Washington, what could be expected from their meeting, more than the usual and almost useless procedure of agricultural societies in general? And if no more should be done, no member would again travel 1000 miles—unless he had other work to do, and private interests to attend to at the seat of government.

It is not that there are not excellent and abundant materials and means at Washington for an agricultural society of more humble pretensions, and yet of far greater utility than this. There are some resident individuals there, whose names appear in the foregoing proceedings, whose general intelligence, zeal for and knowledge of agriculture, would dignify and utilize any properly constituted district society; and such a society would be greatly aided by facilities peculiar to that locality. But these individuals and these means will receive no additional aid by belonging to an organization and plan so ambitious as to be made coextensive with the whole space of our enormous territory.

But whatever may be our anticipations and fears, we shall most heartily rejoice if they shall prove to be unfounded, and the value and results of the "United States Agricultural Society" shall be shown to be equal to the most sanguine expectations of its founders.

VIRGINIA SALT MINE.

From the Journal of Commerce.

I received last week, from my correspondent, Alexander Findley, Esq. of Saltville, Washington county, Virginia, a package containing, among other geological specimens, several pieces of rock salt, or sal gem, which is of a very superior quality. I have left a sample of it at the office of the Journal of Commerce, for the inspection of any person who may wish to examine it. The rock salt is slightly tinged with a reddish color. This is the first salt mine found in the United States east of the Mississippi river and the great lakes, and may well be reckoned a great treasure. The stratum is about one hundred and fifty feet thick and reposes on a bed of plaster rock, and is a little more than two hundred feet below the surface.

The section of Virgima where this salt mine is located lies between the Clinch mountain and the Blue Ridge, and is near the line of East Tennessee, about equal distance from Nashville in Tennessee and Richmond, Virginia. I have also received a sample of most beautiful table salt, manufactured at the salt works at Saltville by evaporation.

I have put up specimens of the rock salt to forward to the state geological cabinet at Albany.

This salt mine was discovered in boring for salt water—and although it is so near the surface, the proprietors find it more profitable to evaporate the brine which yields about two pounds of pure salt to the gallon, in preference to excavating the sal gem. The state of Virginia is rich in her mineral deposites—of iron, coal, salt, plaster and gold—iron, coal, salt and plaster are generally found near together. E. MERIAM.

From the Kentucky Farmer.

RELATIVE WEIGHT OF GRAIN AND COB OF INDIAN CORN.

Bourbon county, Dec, 13, 1841.

To the Editor of the Kentucky Farmer—In looking over your interesting periodical, I sometimes meet with notices of fine ears of corn produced in our country. Now in order to enable your readers to understand precisely how good they were, it seems to me that your correspondents should, in describing them, give us the exact weight of the corn both on the cob and when shelled, as this would afford a very certain standard. The length or girth of the ear, the number of rows or grains, are too uncertain measures by which to determine the excellence of an ear of Indian corn. A reflection of this kind led me while gathering my corn to make the following experiment:

On the 17th November last, without any very great care, I selected twelve of the most remarkable ears that were convenient to hand. The whole, being quite dry, weighed thirteen pounds good weight on the cob. The longest ear measuring thirteen inches in length, but only $5\frac{7}{8}$ inches in circumference was the lightest of the twelve, and contained 742 grains. The shortest ear measuring $8\frac{1}{2}$ inches and $8\frac{1}{4}$ inches in girth, had 22 rows and about 1100 grains—the greatest number of grains on any of the twelve—but the ear was much lighter than many others of the dozen. The heaviest and best ear of all measured only nine inches in length and $8\frac{1}{8}$ inches in girth, containing 18 rows and about 846 grains, it weighed 1 lb. $3\frac{1}{4}$ oz. unshelled; the corn when shelled weighed $15\frac{1}{2}$ oz. I did not consider this a very remarkable ear for size; but the experiment shows how much the eye may deceive us as to the relative value of an ear of corn. Among the dozen there was one ear, selected by several as being decidedly the finest and best. And certainly its appearance was prepossessing, being 12 inches long and $7\frac{1}{4}$ inches in circumference, containing only 14 rows and about 700 grains, which, however, were very large, wide and full. This ear was the second in weight, mark that, weighing 1 lb. 3 oz.; the corn it shelled weighed $14\frac{1}{4}$ oz. having a much heavier cob than its successful competitor. The description of corn is the white flint; and considering that the past season was not the best for corn, I think mine tolerably good. The above experiment has suggested to my mind an important improvement that I think may be made in corn. I intend to try it, and if I succeed will in due time inform you as to the result. I am, respectfully, yours,

JNO. ALLEN GANO.

BROOM CORN.

From the Fourth Report of the Agriculture of Massachusetts.

Broom corn (*Sorghum saccharatum,*) is the next most important crop grown in the county of Franklin. Its cultivation is chiefly confined to the meadows on the Deerfield and Connecticut rivers, though there have been instances of large crops in the interior. Deerfield, Whately and Sunderland in particular grow large amounts of it; and it is said that the prosperity of the last-named town is mainly attributable to this product.

The average yield under good cultivation is from six hundred to eight hundred pounds of brush or broom. One thousand pounds are not unfrequently reached. Six to eight hundred pounds are reported as the average yield in Sunderland and Whately. A crop of seed is obtained about once in four years, and forty bushels of seed are considered a good yield. A respectable farmer in the county informs me that in one instance, he obtained one hundred and fifty bushels of seed to the acre. It is planted in hills at a distance of eighteen inches between the hills lengthwise; and in rows about two and a half feet apart, or at a distance wide enough to pass the plough or the cultivator. By some farmers, broom corn is planted in hills two and a half feet distant each way, and fifteen stalks are left in a hill. It requires good manuring; and is sometimes manured as Indian corn in the hill, or the manure is spread. The cultivation is more expensive than that of Indian corn. No crop is more beautiful than the standing corn, when in perfection; and it frequently reaches a height of twelve to fifteen feet.

The stalks of the plant are long and hard, and therefore difficult to load on a cart. They are generally considered as of no value excepting for manure. This, however, is an error. The Shakers at Canterbury, N. H., among the very best farmers in the country, are as careful to save their broom corn stalks, as their Indian corn stalks for fodder; and, for the feeding of their young stock, deem them equally valuable.

The usual mode of gathering is to table the corn, that is, to cut off the top, or tassel the broom as it is called, about two or three feet from the top, and bending the stalks of two rows together, lay it down and leave it until it is seasoned and fit to be gathered. The brush is then cut, tied in small bundles and carried in. The remainder of the stalks are burnt in the field the ensuing spring, and some little advantage is supposed to be derived from the ashes. Some farmers prefer, after gathering the brush, to cut the stalks and lay them lengthwise in the rows, and plough them immediately under. They will be entirely decomposed by the ensuing spring. A still better mode is to carry them into the cattle and sheep-yards, where they become incorporated with the manure and make a valuable addition to the compost heap. I am satisfied from the experiment of the Shakers, that if properly cured, they might be well applied to the feeding of young stock. It is deemed necessary by the raisers of broom corn to connect with it the feeding and fattening of cattle, that the necessary manure may be procured for the cultivation of this crop.

It is considered a profitable crop when the brush will command five cents per pound. The price has been subject to great fluctuations. Formerly, it was common for each farmer to make his brush into brooms, and sell them when and where he could. This was bad for all parties. It brought too many competitors into the market, and often unduly depressed the price. The buyers likewise were often obliged to put up with an inferior article. The growing of the brush and the manufacture of the brooms are now in different hands. The farmer, as soon as his broom is ready for the market, finds in the manufacturer a purchaser at a steady price; and the manufacturer knows that his reputation, and consequently his success likewise, is concerned in the quality of the article, which he furnishes.

The Shakers for a long time almost monopolized the raising of the corn and the manufacture of brooms, which, like other manufactures of this industrious community, were always of a superior quality and generally commanded a high price, usually 37½ cents a-piece or more. Now, corn brooms are frequently sold from 8 to 25 cents; but many of them are, like Pindar's razors, "made to sell." The handles in an unfinished state, made either of maple or ash, are furnished for a cent a-piece. The wiring and tying on are usually done by the hundred. The scraping the seed from the brush is an unpleasant business, and the dust is prejudicial to the eyes. A common flax comb is generally employed; but an improved machine, moved by horse power is coming into use, performs the work quickly, and greatly lessens the labor. The manufacture, when carried on extensively and with ample capital, has yielded encouraging profits.

The seed is sold at two-thirds the price of oats, and is ordinarily of the same weight. It sometimes weighs more than oats, and by some persons is more highly valued. It is by many esteemed good food for the fattening of swine, when mixed with other grain. Some have used it for fattening cattle and horses, but it is not approved. The saving of the seed of broom corn is, by the best farmers, deemed a matter of much importance. It must be taken from that which produces a full and square head; and not from that which runs up in a spindling form, and "branches like a pine-tree." The difference in the seed is deemed of so much consequence, that while ordinary seed for planting can be obtained at one dollar and fifty cents per bushel, the best always commands four dollars. In no single thing do farmers commit a greater error than in respect to seed. Inferior seed of any kind of plant should never be used; and the difference in the expense between good and poor seed is nothing compared with the increased value of the crop from good seed.

It is a fact, which certainly deserves mention, that broom corn is taken three, four, and sometimes ten years in succession from the same field without diminution of the crop. I have the testimony of three respectable farmers to this point. Yet this can only be done by high manuring. By many farmers it is deemed an exhausting crop. The brooms made from the brush, cut and dried while green, are tougher and much more durable than those made from the brush, when suffered to become quite dry and yellow. The returns of a crop of broom corn in Gill are as follows: the land cultivated was one acre seven rods. The crop of brush was nine hundred and thirteen pounds. Of

seed, there were one hundred and thirteen bushels; eighty bushels of which, sold for twenty-five cents per bushel. This was at the rate of eight hundred and seventy-five pounds of brush to the acre.

I subjoin, also, the exact account of a crop cultivated by Alvah Hawkes, in Deerfield meadows, with which he was kind enough to favor me.

Expense of cultivating one acre of broom corn.

One ploughing the 12th of May, - -	$1 25
Holeing out, one third of a day's work, -	34
Ten loads of manure at 75 cents per load,	7 50
Putting manure in the hills, - - -	2 00
Planting, one day's work, $1; seed, 4 quarts at 75 cents per bushel, - -	1 10
Hoeing first time, 3½ days, $3 50; hoeing, second time, 3 days, $3, - - -	6 50
Hoeing, third time, $2 50; horse and boy to plough for the season, $1 - - -	3 50
Tabling and cutting, 4 days, - - -	4 00
Gathering, carting, and packing away, -	2 50
	$28 69

The expense of cultivating one acre is as above $28,69, the labor being rated at $1 00 per day, which is more than the actual cost. The yield was at the rate of 991 lbs. to the acre. If the ground had been fully stocked, the crop would have been more than 1000 lbs per acre. The brush was sold at 8½ cents per lb. The crop of seed was light and poor; at the rate of 50 bushels to 3 acres; and was sold at 16⅔ cents per bushel or $2 77 per acre.

To the above expenses of $28 69 are to be added as follows:

Scraping 1000 lbs. $3 30; board of man 5 days $1 07, - - - - - -	$4 37
Rent of land, 1 acre, - - - - -	16 00
	$49 06
The sales of the above brush 1000 lbs. at 8½ cts. pr. lb. - - - - - -	85 00
Seed upon above acre, - - - - -	2 77
	$87 77
Net profit per acre, - - - - -	$38 71

This product may be deemed unusual; but there is no difficulty under suitable cultivation in obtaining it. The price is not extraordinary; and had the brush in this case been kept until the spring, it would have brought 12½ cents per lb.

Another estimate by a good farmer, is as follows:

Ploughing, $4 00; dragging, $1 00; manure, $12 00; seed, 25 cents, - -	17 25
Planting 2 feet by 3½ feet apart, 75, -	75
First hoeing, $4 68; 2d hoeing, $2 34; 3d hoeing, $1 17, - - - - -	8 19
Gathering brush and scraping seed off,	12 00
	$38 00
Returns.	
700 lbs. of brush at 8 cents, - -	56 00
40 bushels seed at 25 cents, - -	10 00
	$66 00
Net profit per acre,	$27 81

No charge is here made for the rent of the land.

MANURES. STABLE, COW AND HOG YARDS. HUMAN EXCREMENT.

From the same.

The price of manures in this county is very high. The farmers in the vicinity of Boston depend upon the city stables for a large portion of what they use. The price in Boston varies from three to four dollars a cord. I have known a market farmer to purchase one thousand dollars' worth in a year. Since the value of liquid manure is established, and its intrinsic efficacy is so much superior to the solid parts of manure, it is strange that no provision is made by the farmers for saving the vast quantities that are now lost in the city. Hardly an instance can be found, there is not one within my knowledge, of any provision for saving it at their own barns. This is an improvement yet to be effected. I have urged this matter so strongly, though not beyond its importance, in my former reports, that I shall add little more.

I have known $6 50 paid per cord for stable manure taken at the stable; and a farmer, whose soundness of judgment in other matters I have always respected, expressed his willingness to purchase all the manure from the cow-stable in Lowell at five dollars per cord, though he must then cart it four or five miles in order to reach his farm. These prices are enormous, and the more surprising, since almost every farmer in Middlesex has at hand the means of preparing a compost-dressing for his land of equal value, at not half the cost.

Upon the farms in the vicinity very great quantities are carried from the livery-stables in the city. The hog establishment at West Cambridge supplies a large amount of manure to the farmers in its neighborhood. I do not refer in this case exclusively to the excrementitious matter of the swine, but also to the refuse garbage from the stables, of which I have spoken. This is spread upon their grass lands, or ploughed in on their cultivated grounds, or spread round their apple trees; and in every case with great advantage. If not used immediately, it is placed in a compost heap, and covered with mould, to be used when needed. It has been found particularly useful when applied to fruit-trees at the roots. It is of course full of animal matter, and must furnish in abundance the principles of vegetable life. The intelligent farmer who gives me this account speaks of the effects of this manure as immediate and powerful. To night-soil he objects that its influence is transient. He gives the preference over all others to stable and horse manure. He raises largely of early vegetables and small fruits for the market. The stable manure is more convenient for his forcing beds in the spring, and, after it has performed its part there, is easily applied to other crops.

Large amounts of night-soil are obtained in Boston and Charlestown, and applied by the market-gardeners. It is brought out in a crude state in covered and tight wagons, and too often, without regard either to decency or comfort, is carelessly deposited by the road-side near the dwelling-house in a kind of basin, where a quantity of mould is at hand to mix with it, to absorb the liquid parts, and to put the whole into a condition to apply to the soil. The slovenliness with

which these matters are sometimes managed deserves no light censure. I knew a case in which, in the opinion of his physicians, the life of a respectable individual was a sacrifice to one of these negligently managed deposites made by a neighbor in his immediate vicinity. I do not know why, in a civilized community, the public have not an equal right to claim that the air shall not be needlessly corrupted, any more than the wells in a neighborhood poisoned, whether it be by the effluvia of some odious manure-heap or the scarcely less disgusting odors of tobacco. These places of deposite, as matter of public decency, ought never, under any pretence, to be permitted by the highway. By careful management of them in some suitable place on the farm, remote from the road and the dwelling, this great nuisance might be abated.

I am aware upon what a homely subject I have fallen; but I know how essentially it concerns the farmer's interest and the public health. "Evil be to him who evil thinks." I would advise a fastidious reader to pass over this whole chapter, but that I fear if I did, as it happens with forbidden passages in the classics in college, he would think that he owed it to himself to determine on the propriety of such advice, by first reading with increased attention what the chapter contained.

Every advance in cleanliness is an advance in civilization, a contribution to health and an equal help to good morals. The unfortunate beings who live in cities, are doomed to inhale and exhale the innumerable odors, which are there commingled from cellars occasionally filled with bilge-water, muddocks, which the receding tide has left bare, common sewers, and broken gas-pipes. In the country there is no apology for allowing any thing offensive on the premises. The farmers who obtain the night-soil from cities, would find an advantage in digging a long and deep vault, at least four feet in depth, walled up with stone and plastered and floored so as to be made thoroughly tight, and having a close and moveable covering. Into this the contents of the carts should be carefully turned, with such a constant supply of soil or muck or ashes or effete lime or gypsum as would completely absorb the liquid parts, and might be so intimately incorporated with the solid parts as to bring all into a feasible state of application to the land. This vault or stercorary should likewise serve as a place of deposite for all dead animals in the place, and all other offensive matters, which might be converted into manure. The contents of the family vault, being freely mixed with mould or spent tan, should likewise be conveyed there at least once a week. This would be a great gain to comfort and health. I saw much an arrangement on one farm, and its advantages were most obvious. It formed an excellent bank of general deposite, whose discounts in the spring were always most liberal and useful.

The preparation of night-soil for easy use and transportation, has been the subject of various chemical experiments. The prepared article goes under the name of poudrette; and though there have been occasional disappointments, I have seen it used with great success. The admixture of effete or slacked lime with it has the same effect as any other absorbent; but the application of quick lime, while it destroys its offensive odors, expels its ammonia and proportionately reduces its value. Liebig recommends its mixture with gypsum or chloride of calcium, or some mineral acid. I have not known this tried. This would fix the ammonia and give it out to the plants as the vital process is prepared to take it up. The mode of preparing it in Paris, is by drying it in large vats in the sun until it can be reduced to a fine powder and loses all smell. Its best properties are then gone. Fine peat, muck, fine mould, powdered charcoal, tanners' bark burnt and charred, are substances which may be mixed with it to great advantage. It is beyond all question one of the most powerful of manures, but can only be applied advantageously in a prepared state. An establishment for this purpose is about being made in the county which may prove eminently beneficial.

Bone manure has been tried to some extent; in some cases within my knowledge, with great and decided success; in others, without perceptible benefit. These diverse results convince us of our ignorance, and show how much we have to hope from the investigations of chemistry and philosophical experiments in relation both to manures and soils, and the hitherto scarcely approached mysteries of vegetable life. Much of the bone manure which has been used has been from bones which have passed first through the hands of the soap-boiler, and after all the gelatinous parts have been extracted. A considerable portion of their fertilizing properties has thus been taken away. The most successful application of bone manure which I have known was where they were mixed at the rate of about one part to eight with leached ashes or mould, and a fermentation brought on before they were applied. They were then spread lightly in the furrow, where carrots were sown. The effects were most favorable, and surpassed a free dressing of barn manure in the neighboring part of the field to the same kind of crop. I have known this manure applied likewise with great advantage to corn in the hill, a small amount in each hill without other manure, and to turnips in the drill. Peat mud is used with much success by many persons. Its application, when spread directly from the bog upon the soil, has not been approved; but when it has been thoroughly decomposed and reduced by a mixture with stable manure, with ashes, or with quick lime, it has furnished a valuable manure for spreading upon grass ground or putting in the hill with corn.

Various other manures have been used with great success. Ashes are every where commended as excellent for corn and wheat, and likewise for grass. Ashes being the direct result of vegetable combustion, contain of course that which is essential to vegetable growth and life, and being constantly carried from the earth by the removal of its vegetable products, must in some form be returned to it.

In some cases the waste from the cotton mills has been used with much advantage. This consists of that which is thrown out when the cotton passes through the picker, and is made up not only of the wool itself but a considerable amount of the seeds, which are known to abound in oil, and at the south are much valued as a manure. This manure is sometimes spread thinly on grass land, and at other times put into the compost heap. It has been too little employed for us to

determine the best mode of its application. The waste from the woollen mills has likewise been used as a top-dressing for grass both in Tewksbury in this county, and at Northampton in Hampshire. I have seen its effects in these places and in some other parts of the country. They have been most remarkable, and surpassed by no manure which I have ever seen applied. This refuse used formerly to be accumulated in the neighborhood of the woollen factories at Lowell; and being surcharged with oil used in cleansing it, there was great risk always of spontaneous combustion. When thrown into the river it was complained of as interfering with the shad fishery. The amount of wool used at the Middlesex mills in Lowell is more than 600,000 lbs. per year. Being full of animal matter it is a most excellent manure. Its value has long been appreciated in England, but we seem to have come late to the knowledge of it. I have seen it spread directly upon grass land, both in mowing and pasture grounds, with surprising effect. It is much to be desired that the water in which their wools are washed, full as it is of animal oils and alkalies, could likewise be saved and applied to the land. It would prove beyond doubt a most valuable manure either applied on the grass lands or mixed in the compost heap. In the economy of nature nothing is without its use; and the first duty of the farmer is to remember that nothing should be lost.

A very exact and intelligent farmer in Groton made some comparative experiments with different manures on pieces of land contiguous to each other, of which he has favored me with an account. The land to which these different substances were applied was what is there termed reclaimed meadow, and rich in vegetable mould.

One bushel of ashes applied to three square rods of land at the rate of 53 bushels per acre; this produced a heavy burthen of grass, and was considered the best of the several manures applied.

Salt, applied at the rate of one peck to three rods, or fourteen bushels per acre, produced a fair crop, and was considered the next best to the ashes.

Gypsum, sown at the rate of three bushels to the acre, manifestly much improved the crop, and was much the least expensive application. Lime was dry slacked and applied at the rate of one bushel to six rods, or 26 bushels per acre, without any perceivable effect.

I do not present these examples as furnishing any decisive results, but rather with the hope of inducing farmers to make and record exact experiments, though on a very limited scale, that by the accumulation of such facts we may arrive at something more definite. Little can be deduced from the above experiments, unless equal quantities of each kind of manure had been used; and then we want likewise to understand the nature of the soil, as in respect to some soils it is obvious certain kinds of manure are much more suitable than others.

COMPOST MANURE, PRINCIPALLY OF PEAT OR SWAMP MUD (OR MUCK.)

From the same.

D. S. Haggerston, the intelligent and experienced manager of J. P. Cushing's garden and farm at Watertown, has been kind enough to favor me, at my request, with some practical observations and experiments on the subject of manures, which deserve attention, and are therefore subjoined.

"I send you an account of experiments made on the farm of J. P. Cushing, Esq., of the different composts used as manures, and the apparent effects of each.

"Meadow muck or peat has been used in various ways, and found so very beneficial, that two thirds of the manure used on the farm is dug from the swamp.

"A compost for top-dressing mowing land is made from leached barilla ashes from the soap-boilers', and meadow muck, in the following manner. The muck is dug from the swamp, the last part of August, or early in September, and lies one year on the surface, after it is thrown out of the pit. It is then carted to a convenient place to make the compost heaps, which are formed by spreading a layer of muck ten feet wide, eight inches thick, and of any length desired; on the muck four inches of ashes are spread, then another layer of muck, and so on for five layers of each, which makes a pile five feet high, in the form of a ridge. This is to lie through the following winter. As soon as the frost is gone in the spring, the pile is turned over, well broken, and mixed together. It then lies till the October or November following, when it is spread on the land at the rate of fifteen cart-loads to the acre.

"Two accurate trials of the above compost, in comparison with decomposed stable manure, resulted as follows; 4 squares of equal size which are kept as lawns and mown seven or eight times in a season were manured, two with the leached barilla and muck compost, and two with a compost of well-rotted stable manure. It was spread at the rate of twenty cart-loads to the acre. The grass on the different squares was much the same in quantity, but on the squares manured with the muck compost, it was decidedly of a darker and richer color, and the manure introduced a greater quantity of white Dutch clover or honeysuckle. The second trial was in a field mown for hay, 2¼ acres. The field was divided into two equal parts, as near alike as possible, one half manured with muck compost, the other half with rotted manure, at the rate of fifteen cart-loads to the acre. Eight tons and eighty lbs. of hay were cut from the field. No difference could be discovered in the parts manured by the different composts. This proved that, for a top-dressing, the compost of leached barilla and muck is equal to stable manure. After using it to a large extent for several years, I am still in favor of it as a top-dressing. The compost manure, which we use for ploughed land, is made up of two thirds muck, and one third manure. The muck in all cases is mixed with the manure before it ferments, and care is taken not to put in so much muck as to prevent the compost's heating. The fermentation of the manure decomposes the muck rapidly, and I am

convinced the greatest art in the use of muck, as a manure, is to have it in a proper state before it is put upon the land. To dig it from the swamp and apply it before it undergoes a chemical change is undoubtedly injurious. This change is brought on rapidly by hot horse manure or unslacked lime, but with colder substances it requires longer. For mixing with cow manure, or putting in hog sties, it ought to be dug from the swamp, at least six months, and it is better that it should be exposed to a winter's frost, before it is used. The air then, in some measure, effects the change. The action of the manure soon decomposes the fibre in the muck. It falls to pieces like lime, and then has an earthy appearance. In this state, a mixture of one third manure and two thirds muck has never failed with me to produce better crops of all kinds of vegetables than clear manure. For the last five years we have thought it wasteful to use manure without being mixed. Before coming to this strong conclusion of the benefit of muck, when used as a manure, many experiments were made, and universally resulted in favor of muck."

SALTPETRE AS MANURE.

From the same.

Saltpetre has been used to some extent in Middlesex county. The use of this manure and the nitrate of soda, abroad, has, according to the reports which we have had, been productive of so much benefit, that every fact connected with their application here is important. I shall subjoin some few of the results which have come within my knowledge.

E. Phinney of Lexington thus writes to me:

"My experiments with saltpetre as a manure have satisfied me of the inexpediency of using it for that purpose. In the spring of 1839, I purchased 400 lbs., for which I paid $8 per cwt. I tried it upon wheat, rye, and grass. Fifty pounds to the acre on wheat and rye had no perceptible effect, and on grass but very little. One hundred pounds to the acre occasioned a very considerable increase of straw and grain, both in wheat and rye as well as grass. But had I bestowed an equal outlay in compost made from peat-mud and stable manure, or peat-mud and ashes, I have no doubt the immediate crop would have been more benefited and the land have received more permanent improvement. I have in one instance seen very striking effects produced by the use of saltpetre upon a light, sandy soil. But the quantity used I could not learn, any further than that it was much greater than the quantity to the acre used by me. I believe a portion of saltpetre and common salt, say ten pounds of the former and twenty pounds of the latter to a cord of compost manure well mixed, would greatly improve it. The beneficial effects of saltpetre in the destruction of insects that annoy our crops, cannot be doubted. I noticed on the farm of Mr. Whipple, of Lowell, two orchards separated only by a stone wall. The trees upon one side of the wall were badly eaten and almost destroyed by canker-worms, while those upon the other side were untouched. On inquiring the cause, I learned that saltpetre had been used upon the land of the latter orchard and none upon the former. The remedy may be an expensive one; but were my trees attacked by this terrible scourge, I should immediately apply it. The saltpetre, instead of injuring the trees, as most applications do which are made for this object, would greatly promote their growth."

I think proper to subjoin here, though from another county, the experiment of John E. Howard, of West Bridgewater, Plymouth county, an account of which he was kind enough at my request to furnish me. Mr. Howard's exactness and intelligence are well known.

"You expressed a wish to hear further concerning the experiment which I made the past season, to test the efficacy of saltpetre, when applied as a top-dressing to grass land.

"Of the patch selected the soil is a light sandy loam. On this, some time in the latter part of May last, I sowed saltpetre at the rate of one pound to the square rod. The effects were soon visible; the grass exhibiting a deeper shade and a more luxuriant growth than in any other part of the lot. It continued to grow thriftily until the period of its maturity, when, on cutting it, the produce was judged to be double that grown on any equal number of feet in the same field. The beneficial action of this substance, however, seems not to have extended beyond the first crop; as, since that was removed, no appearance of superior fertility has marked the spot where it was spread."

O. M. Whipple, of Lowell, the proprietor of a large establishment for the manufacture of gunpowder, in which much of this material is used, has favored me with successive communications on this subject, which I can do no better than present in his own language.

"It is now about sixteen years since I commenced using saltpetre. The grounds upon which I have used it, have yielded large crops, and have held out much longer than grounds in general, of the same quality of soil, and of the same kind and quality of dressing commonly used.

The kind of saltpetre which I have used has been that part extracted from the common saltpetre while undergoing the process of purification, and is not fit for gunpowder. I have, therefore, not been particular as to quantity, using what I have had to spare; but I am satisfied that it requires but a very small quantity to produce favorable results; I have thought that one hundred and fifty pounds per acre would be a sufficient quantity to be used generally. The best mode of using it is to mix it with barn manure, meadow mud or any kind of compost which may be at hand; although I have used it in various other ways, as I shall now describe.

I have one piece of ground of 2¾ acres. It had been used for a long time as mowing ground, and had, as it is termed, run out, and grew but a very small crop of grass, say 1500 lbs. to the acre, I ploughed it in the fall of 1830; in the spring of 1831, I covered it with barn manure, mixed with saltpetre, as described above, and harrowed it in, and planted corn without disturbing the furrows. I had a very handsome crop of corn. In the spring of 1832 I again dressed it as before, that is, with barn manure and saltpetre, sowed oats and stocked it down. The oats were

good. In 1833, I took from it a crop of grass, which was estimated to be six tons. It has grown grass every year since, and I believe not a less quantity than the estimate above has been taken from it since the first crop. I should be safe in saying that there were six tons grown upon the lot the last year, and this year the crop is good. I have another lot, containing 1¾ acres, which like the other yielded little grass; 20 cwt. being all the lot produced in 1822. In the spring of 1824, I dressed it upon the surface with manure, meadow mud, and saltpetre mixed; and it yielded a moderate crop that year. In the spring of 1825, I sowed upon the surface, as you would sow rye, a quantity of saltpetre. The result was, that I took from the lot at least four tons of hay, as it was adjudged. This too was in a lot containing apple-trees, and the grass much lodged all over the field. I continued sowing upon this lot a small quantity of saltpetre once in two years, for five or six years, and at the same time raising a very large crop of grass yearly. Nothing has been done to this lot for the last six years, and there is at this time upon it more than a middling crop of grass.

"I have another lot of light-soiled ground, of about four acres; it had been used for growing rye. It occurred to me that I would try the experiment of saltpetre upon a small piece of this ground. The result was so favorable, that the next year, in the spring, I covered the piece with meadow mud mixed with saltpetre. The result was, that I obtained from the ground as large a crop of grass as it was considered profitable to raise. Last year, which was the fifth, it yielded two tons per acre. There has been, however, a small quantity of saltpetre sowed upon the lot since. I could describe other lots upon which saltpetre has been used, but with the same results as those already mentioned.

"I shall now designate the above lots and describe the kind of soil.

"The first is No. 1, of a middling quality, neither very wet nor dry.

"The second, No. 2, is an orchard adjoining Concord river, of a damp soil and of a very good quality.

"The third is No. 3, a dry, sandy soil, considered by me of no value, until I practised using saltpetre upon it as a dressing. With regard to the mode or manner of using saltpetre upon ground, I do not think it makes much difference, if it is but put upon the ground. I have practised sowing it upon the surface, and mixing and ploughing it in with, for aught I know, equal results; but I should be rather in favor of mixing and ploughing it in. In this case it would require a larger quantity, say 300 lbs. per acre; the effects would be more slow and lasting. In sowing upon the surface, it would require a less quantity, say 150 lbs.; but it would be necessary to repeat the dressing yearly, until the crop should be satisfactorily large. I am more in favor of bringing up the ground gradually, by the yearly application of a small quantity of saltpetre, than I should be by a larger quantity, and getting a large crop the first year."

Since the foregoing, the same farmer has furnished me with some additional information, which follows; and again, the present year, assures me of his continued success in this application. I could have wished that the experiments had been made with more exactness.

"Since my communication to you in June last, respecting the use of saltpetre as a manure, I have had a more particular practical demonstration of its utility.

"Having an island in Boston harbor, called Spectacle island, and its distance from land rendering it very expensive to furnish manure for it, in the spring of 1838 I concluded to try the experiment of using saltpetre as a substitute, and in order to test its ability with some exactness, out of two acres which had been cultivated the year before, half an acre was set apart for the purpose of receiving 150 lbs. saltpetre, which were sowed on the surface and the whole two acres were then ploughed and planted with potatoes. At harvesting, I found that there was an increased crop upon the ground where the saltpetre had been applied. I directed the man in charge to dry 5 hills upon the ground where the saltpetre had been applied, and also 5 hills where there had been no saltpetre, and weigh each parcel. The potatoes on the ground where the saltpetre was applied, weighed 9 lbs., the other 4 lbs. This, it will be perceived, was the result of one year's application only. I am inclined to think that its influence will be felt more or less the second, or even the third and fourth years.

A field containing two acres from which grass had been taken for 8 years, I had ploughed in the spring of 1838, once only; it was ploughed deep, and 90 rods were appropriated to the growth of ruta-baga. The seed was sown upon the tops of the furrows, without any manure in the drill, and the result was, that I obtained 500 bushels of the article specified above; the remainder of the field was sown to oats, but the crop was mostly destroyed by the unexampled growth of hog weed. This field had been wholly sustained by the application of saltpetre upon its surface, previously to its being ploughed, excepting at the time of ploughing, when there was turned in a small coat of manure."

WHITE HOGS.

From the Farmers' Cabinet.

Mr. Editor—It is really amusing to find that many of our friends are beginning already to *turn up their noses* at the black Albany Berkshires, and express a strong preference for Mr. A. B. Allen's white *Kenilworths*, wondering if that gentleman will have a sufficient supply for all his customers the next season? And I have heard some apologizing for having gone into the black Albany breed, by declaring they *never liked them*, always having had a strong prejudice for a white hog—and so we go on. But I suspect the *Kenilworth* harvest will not be so profitable as has been the Berkshires, for nothing will be more easy than to compete with the Kenilworths by means of our own Chester and Delaware county white breeds; and I am sanguine in the belief that we shall be able to convince all disinterested persons, that so far as that distinct breed is concerned, our intelligent friend Allen might just as well have remained at home; and of this he might convince himself, by taking a journey to these parts, at a com-

paratively trifling sacrifice of time and money. And I take the opportunity of introducing to the notice of those who, having tried the Albany Berkshires, and found them wanting, a breed of hogs now in the hands of Mr. William Reybold, Delaware state, which, or I am much mistaken, will not be found at all inferior to the imported Kenilworths, if they be not much superior, as I strongly suspect they will prove. They are perfectly white, too, and soft-haired, with the deep side of the old tawny Berkshire, cutting up nearly as thick in the side and belly as on the back, which is, I guess, about as much of an *antipode* to the black Albany, as the color of the breed. Mr. W. Reybold is the son of Major Philip Reybold, the breeder and feeder of those superlative Leicester sheep which were slaughtered at Baltimore the last season, several of which weighed over 40 lbs. a quarter, dead weight, at the age of two years; and Mr. Allen would find that the major's present stock of fat wethers would vie with any of the thoroughbred varieties in England, of any name or county. And I cannot but suspect, from the perusal of Mr. Allen's letter, that the time *has come* when we may take our stand and breed from our own stock, without being beholden for any more help from abroad; for indeed it is curious to observe how very small have been the importations by this first of breeders and judges of stock, which, as far as I can learn from his letter, amount to *five* pigs of the Kenilworth breed, "three of them from a smaller and coarser boar, and from sows still less!" But what our friend means by stating that "he was informed this was always the case with this breed," I am at a loss to conjecture. It might disclose my ignorance, perhaps, were I to ask, if this admission be meant as a recommendation or otherwise, of this particular breed? To these are to be added the number of Berkshires brought, which is not stated in his letter; the sheep for Mr. Rotch, Mr. Stevenson, and Bishop Mead; one dog, of a sort which requires *no instruction* to break into the management and care of a flock—which no one will believe who knows any thing about the matter—a few Dorking fowls, with extra toes to their heels, sometimes attaining to the *great* weight, when fatted, of 8 pounds—and a few pheasants! Of short-horns he brought none, and confesses that it pains him to see so many Durhams of ordinary quality imported; and as for horses, "England ought to come to us!" What, for carriage horses, the present racing blood, and the high-bred hunters? Try again, friend Allen.

On the subject of the Dorking fowls, I would just say, if Mr. Allen had come on to Jersey state, he would have found that Mr. Wood, of Haddonfield house, could "beat that hollow," not sometimes, but always, many of his chickens weighing more by a couple of pounds than the great weight he mentions. He is in error in the statement that the game cock of England is from a cross with the pheasant; if he had seen any of that particular cross, he would have known better. If I could say what I wish on the subject of the travels of our eastern friends, without fear of offence, I would just hint the probability of their being more gratified, and of reaping more wisdom as well as profit, by going abroad in their own country, rather than by visiting foreign lands in the expectation of speculating in stock, a very precarious business at best. Mr. Allen complains of the enormous expense of shipping animals from England. I fear if his expenses of travel were to be spread over the few animals which he has brought over, the account would deter many from making the experiment in future. I wish that we could for once come down to the improvement of our breeds of cattle without the vile spirit of speculating for money; but that has been our easily-besetting sin, from the time of the Merino-mania to that of the multicaulis and the black Albany Berkshire fever. "All wrong, depend upon it."

I have heard that when John Lossing found that A. B. Allen had gone to England to import big Berkshires, he had the precaution to sell out his Albany Berkshires, making a profitable speculation of it. That was wise; for he may now either go back to the breed by which he has made thousands of dollars, or *forward*, into the Kenilworth; and as he knows so well how to "strike the iron while 'tis hot," he may make capital stock by commencing with such hogs as those described by Homer Eachus, at p. 329 of the Cabinet, vol. v., which might be denominated the improved-improved Kenilworth white Berkshires; he will not be at a loss for individual names, for there may as well be $300 *white* Maximas, as black ones; but he had best be quick about it, for in this part of the country, where that breed has long been known and properly appreciated, persons may be found who will "hit the right nail upon the head," and go into the business at once.

G. H. D.

Chester county.

BUTTER.

From the Halifax Colonial Farmer.

The Low Dutch inhabitants of Long Island were accustomed to churn their milk instead of the cream, as habit had taught them to prefer buttermilk to sweet skimmed milk. They consequently churned every day; the morning and evening's milk was put into a very large and very clean churn which was placed near the fire, and securely covered, always putting to it a small quantity of coagulated milk. As soon as the milk was all coagulated, which it generally was by nine o'clock the next morning, it was carried to the milk-room and emptied into the churning churn, adding one third the quantity of warm water. The woman churned with her foot, as she was accustomed to turn her flax-wheel, the dasher being lifted by a spring-pole, such as is affixed to the most simple kind of turning lathe. While churning, she was always knitting, for a Dutch woman will never lose any of her time. The churning was generally completed in half an hour, the buttermilk was then strained off, and the butter turned into a tray; then taking a large wooden ladle with a handle about half a yard long in each hand, she took up in the ladle in her right hand about a pound of butter, which she tossed up five or six feet high, catching it with her ladle as it fell, two or three times; and then with a smart stroke at arms' length, struck it into the ladle in her left hand, when after changing hands, and tossing and catching it again, she deposited it in a tray previously rubbed with fine salt, and com-

menced with another lump. This work is performed with remarkable agility even by old women. I think that I have seen a woman of sixty work the buttermilk out of ten pounds of butter in this way in less than five minutes? The butter is then cut to pieces with the edge of the ladle, the proper quantity of salt taken up in a horn spoon and sprinkled over it, and worked into it by chopping, tossing and catching and striking it from ladle to ladle (for a Dutch woman never touches butter with her fingers.) She then with the ladle places in a balanced plate in her scales the quantity she means to have in a print, and when it is weighed, gives it a neat figure by tossing and catching it, and then with a smart stroke of her paddle brings it upon the print which is held in the left hand, having a long handle like the ladle.

As we have some of the descendants of the Low Dutch in the county of Annapolis, it is to be hoped that they retain the ancient practices of their mothers, who were well qualified to give useful lessons to many of our countrywomen upon other parts of housewifery as well as upon managing the dairy.

Many women who make good butter have the custom of skimming their milk the same morning that they churn, and mixing the cream with that which they are about to churn. This cream is left in the buttermilk, for it will not make butter till it becomes sour. Of this any persons who follow this practice may convince themselves by allowing their buttermilk to stand twenty-four hours and then churning it again.

When the strippings (the last milk taken, after three-fourths or more have been milked) are mixed with the cream, it should be allowed to coagulate before it is churned, or else a part of the butter will be left in the buttermilk. The stripping or last milk, and the first cream that rises, make the best butter. The salt used for butter should be of the best quality. That which turns damp in wet weather is not fit to salt either butter or pork. This dampness is caused by muriate of lime, a salt of which there is a small quantity in sea-water; it will attract an extraordinary quantity of water from the atmosphere, and always weaken the brine in which it is mixed.—When good salt cannot be procured, the damp salt may be freed from the muriate by the following process: make a strong brine with some of the salt, let the salt that is to be refined be put into this brine for a day, stirring it occasionally; then pour off the brine, put clean water to the salt, stir it for a few seconds, pour it off and dry the salt in the sun. To make this process intelligible, it should be observed that brine so strong that it can dissolve no more common salt, is still capable of dissolving a considerable quantity of muriate of lime.

To make good butter from milk of thin ridge-backed cows in hot weather, the milk should be scalded as soon as it is strained; the cream will then rise as thick as that of muscular broad-backed cattle, and make nearly as good butter, and the churning may be performed in less than half an hour. Care should be used that the milk is neither burnt or smoked; for this reason the pot should be set on coals, and not allowed to boil.

One part sugar, one nitre, and two good salt, will preserve butter, almost unchanged for a long time; but the butter must not have been washed with water, and when packed it must be secured from the air by covering it with a cloth dipped in melted butter, the edge of which must be soldered to the tub or crock with melted butter.

Charcoal if it could be used without difficulty has a more powerful effect in preserving butter than any kind of salt. When a boy I had occasion to see many firkins of Irish butter opened which had been kept long in stores. A part of the casks were burnt to a coal on the inside. In all these the butter was perfectly sweet; in all those that were not burnt, it was very much damaged.

THE AGE OF CATTLE AS SHOWN BY THEIR TEETH.

From the Kentucky Farmer.

My attention has been drawn to this subject ever since our Winchester fair. One of the judges appointed upon that occasion examined the teeth of several of the cattle that were presented there, and pronounced them to be older than represented.

Some of these cattle were bred in this country, and *I know* that their ages were correctly stated.

At Paris, the treatise upon cattle with the plates was introduced by one of the judges, and the teeth of some of the animals were examined to see if they corresponded. This led to suspicion that there had been imposition in some of the cattle presented.

Since that time I have examined the teeth of a number of thorough-bred Durhams whose ages I know to a day, and have found that in this stock their teeth would make them appear to be about four months in each year older than they really are. A three year old will have the teeth that in the treatise upon British cattle is said to belong to a four year old.

I attribute this to the early maturity of the Durham stock. It is reasonable to suppose if they get their growth sooner than other cattle that they will also shed their teeth sooner. I have said about four months to the year, which was the case generally. Some showed even a greater difference.

SAMUEL D. MARTIN.

BERKSHIRES.

From the Farmers' Cabinet.

Mr. Editor:—So much has been said and written about the Berkshire hogs, that people have procured them, at a heavy price, merely because they have been highly recommended in the agricultural papers of the day, and because it has become fashionable to have them, so that when a friend drops in, why, if you have nothing else to show, you must fain show your Berkshires. Now, what I am going to say will no doubt raise the hue and cry of the whole fraternity of Berkshire breeders. Yet I care not: what I seek are facts, and these must be told, and cannot be controverted. I am a subscriber to your valuable

paper, and as such, I have always been pleased to see that your columns are open to a temperate discussion of matters and things, even when men do differ, and this fact is the cause of my troubling you for the first time with my observations. This is, however, digression. In the first place, then, the Berkshire hogs are not what they have been "cracked up to be." I have a neighbor, who has given them a fair trial, to which I have been an eye-witness. The experiment was made in this way:—two Berkshires were placed in a stable with two of the common breed, all of the same age, and were carefully fed, and at the end of nine months they were killed, and the result was, that the common breed exceeded the Berkshires in weight, one fifty and the other sixty pounds. Experiments have been made, to my knowledge, in other instances, with similar results, and even with worse credit to the far-famed Berkshires. They are not prolific: a gentleman of my acquaintance had four sows, each of which had but *one pig*, being a loss of at least ten per cent. a head, and the generality of them, I believe, do not get more than four or five. The only redeeming quality which they possess is, that they fatten easier and quicker than some breeds of the native hog; but even this is counterbalanced by their diminished weight when slaughtered. They may be considered an improvement on the common China hog, and that is about all. I have a number of common hogs in a pen for killing, which are but nine months old, but they will weigh 300 pounds a-piece by Christmas; they have been fed on nothing but the offal of a kitchen, and a run at grass, until within about four weeks, since which they have been fed on corn and boiled potatoes. Considering their feed—for after all that makes the hog—these hogs of mine will challenge competition with any Berkshires in the land, for symmetry, heavy hams, finely turned shoulders, thick and deep in the sides, &c., &c. I purchased them when small, but not being aware of their qualities, I did not preserve the breed; I shall, however, endeavor to get others, and by a judicious crossing, I have no doubt they will make a far superior hog to the Berkshire, which a number of my neighbors have given up, preferring the best of the common kind to them, and in so doing, I think they are perfectly right. I have no disposition to discourage the propagation of a superior breed of animals; on the contrary, I would do all in my power to further so laudable an object; but the Berkshire pig mania, like the mulberry speculation, is upon the wane, and if A. B. Allen, of Buffalo, New York, has in his late trip to England, brought no better specimen of improved animals than Berkshire hogs, he might have saved himself the risk of a ducking in the Atlantic for such an object.

R. S. B.

Hanover township, Northampton Co., Pa., Dec. 5, 1841.

AGRICULTURE VERSUS COMMERCE.

From the Farmers' Cabinet.

Mr. Editor:—On reading the article of your city crrespondent, G. M., in the last number of the Cabinet, I have been led to the conclusion that the writer is either an extravagant liver, or that mercantile business is not what it has been "cracked up to be." He informs us that he invested $15,000 in the year 1827 in commercial business, and has been considered ever since a *successful* merchant, and that for the fifteen years he has been in business, his living has consumed all the profits, and that he is now not worth more than when he began, if so much.

Now, if that living which has absorbed all the profits of a business with a clear capital of $15,000 has been an economical one, I should say that the sooner the capital is diverted to another channel of industry, the better; and as your correspondent wishes to escape the reverses incident to his present business, and seems desirous to turn his attention to the independent and noble pursuit of agriculture, for which he is prepared, at least in *capital and theory*, I would, therefore, for his information, and that of like inquirers, contrast his mercantile operations, and the results as given by himself, with the agricultural operations of my neighbor, S. G., and their happy results worked out, through an experience of 17 years, on land that in this section of the country is considered *naturally* third rate. Mr. G., by close application for some years to a mechanical trade, and at the same time living economically, accumulated a considerable sum, with which he purchased a poor farm of about 130 acres, and the *necessary* stock for the same, which consisted of a yoke of oxen, a horse, and two cows. In conveying an idea of the condition of this farm, I could not use language more significant than that used by Mr. G., when speaking on the subject of his commencement in farming. He stated, that his farm was *so poor* when he purchased it, which was in the spring of 1824, that "he did not believe that his two cows, pair of oxen and horse, got a belly-full of grass on the farm the first summer." This poor land cost him 30 dollars per acre; his stock and farming utensils amounted, perhaps, to about $400; this will increase the investment to $4300. The farm-stock and utensils, he informed me, "he had *about clear*." The first year he put on this worn out land 2000 bushels of lime, and the manure made in the yard the preceding winter, which was carted out with a yoke of oxen in less than a day. This lime was spread on the land at the rate of 100 bushels to 3 acres, or 33⅓ bushels to the acre; and from an experience of 17 years, he finds that a top-dressing of about that quantity repeated every five years, keeps the land in a better condition than when put on in larger quantities at more distant periods. But this experience, it may be remarked, has been altogether confined to the treatment of *mica slate land*. The lime acted with magical effect. The manure-heaps, (the farmer's gold mine,) which in the fall of 1824 had been *quarried* out, and carted on the land with a yoke of oxen in less than a day, increased, until double that power was required from ten days to two weeks to remove it from the yards and stables. The capacity of the farm to support animal life consequently increased; and in a little time Mr. G. stood by the side of his more favored neighbors as a respectable farmer, no more to receive the jocular expressions of "poor farm," "starved stock;" and the thousand and one mortifying thrusts of home-spun wit and neighborly jest. Actuated by the right agricultural spirit, he has continued his

excellent treatment of repeated liming and manuring, until he has brought his farm into a state of improvement for grazing, and indeed for any other purpose, equal, perhaps, to the best land in the country. He has fed this year upwards of 40 head of cattle; and as an evidence of the capacity of his farm to produce grain, his field of corn, containing about ten acres, averaged about 85 bushels of shelled corn to the acre. In speaking of the powerful effects of lime as a fertillizer, Mr. G. made the remark that "*if lime put a man in jail, it would soon take him out again.*" Thus conveying a good deal in favor of that valuable mineral in a few words. But is it saying too much? Every experienced agriculturist in this section of country, I am inclined to think, will unite in opinion with my neighbor G.; and I believe that if the truth conveyed in the remark were impressed more generally, we should find through the country more good land, and hear less complaint of hard times. We now have the case presented, of an investment of $4300 in agriculture, and a successful and judicious pursuit of the same for 17 years; and what is the result? First, a good living for a large family. Second, an increase of the value of the farm from $30 per acre to $90 per acre. Third an increase in the value of stock and farming utensils, from $400 to from $1000 to $1200. Fourth, several thousand dollars at interest, as profit from the farm on good security—not bank stock—besides suitable marriage portions to several of his children. I have now drawn the contrast, and without comment, would conclude by observing that Mr. G. is worth from $15,000 to $20,000, without a creditor; and is now enjoying his *otium cum dignitate* in the character of "Gentleman Farmer."

POA VIRIDIS.

Goshen, Chester county, Dec. 9th, 1841.

HINTS ON POISONS.

By Thomas D. Mitchell, M. D., Professor of Materia Medica and Therapeautics in the Medical Department of Transylvania University.

From the Kentucky Farmer.

Lexington, Ky., January 4th, 1841.

Dear sir:—Hoping that the hints and facts herewith communicated, may lead to further and more stable conclusions on the subject of *milk sickness*, than any that have yet been formed, I extract them from a manuscript work on *poisons*, in which I have been for some time engaged. You will perceive that they have no claims to methodical arrangement, and have not the charm of novelty to commend them to public notice.

That milk may be poisoned, even without criminal design, is now well understood. The milk pans in use in Europe, and to some extent in this country, have often imparted a deleterious quality to cream, and consequently to butter. Many facts directly in point could be cited from the best authorities.

But the most fruitful source of injury to milk is that agent, whatever it be, that gives rise to the disease so common to the western country, and called *milk sickness.* This unexplained source of mischief has perplexed not only the common people, but men of science, all over our own country, and not less the learned and unlearned of Europe. Hence, the inaugural dissertations, that have been repeatedly written by candidates for graduation in medicine, the numerous essays of practising physicians, in various sections of the union, and the elaborate disquisitions of eminent Germans and Frenchmen, on this recondite question. And yet, the darkness that envelopes it is dense as ever; and we see not that science promises much to dissipate the gloom.

Christison justly remarks, as others had done before, "that the milk of the cow, the ewe and the goat, may act like a virulent poison, although no mineral or other deleterious impregnation could be detected in it; and these effects have been vaguely and variously ascribed to the animal having been diseased, or to its having been fed on acrid vegetables, which enter the milk without injuring the animal, necessarily." And Orfila, to whom in conjunction with Mare was entrusted the examination of goat's milk that had proved poisonous to many persons, reported, "that no mineral poison could be detected; that none of the usual explanations were satisfactory, and that the *poisonous change in the milk should be ascribed to new principles, formed or developed by a vital process.*"

The conclusions just stated are, it may be, correct; yet there is reason to believe that the poison may be derived from some kind of vegetable matter, which could not be detected by chemical tests. Dr. Westrumb, who wrote on the poison of cheese, held this opinion; and conjectured that the milk was poisoned by the cattle partaking of a species of spurge, (*Euphorbia esula,*) which, agreeably to Viridet, caused certain fields in the neighborhood of Embrim to be abandoned by the shepherds, because it rendered the cows' milk useless. The same writer also observes, "that the cows would not touch this plant so long as wholesome pasture was within their range."

The symptoms, in the cases already referred to, as having occurred in France, were those often seen in violent cholera. At Hereford Westphalia, where, according to *Rust's Magazine,* for 1828, a woman and her 5 children were poisoned with goat's buttermilk, sent to them by a charitable neighbor, the symptoms were violent puking, dilated pupils, the eye-lids half closed, pulse small, hard and slow, epigastrium turned, abdomen contracted, bowels unmoved. These, as will be seen, were not unlike the symptoms of milk sickness, in this country. Lukewarm water was given, to increase the vomiting, after which two ounces of medicated soap, dissolved in a pint of water, with the addition of an ounce of almond syrup, were administered, and the bodies of the patients were washed with vinegar and spirits. In ten hours, all the patients were recovered.

The most careful examination of a portion of the buttermilk that had poisoned the family, failed to detect any trace of mineral poison; and the physician attributed the mischief to some narcotic herb, probably the *Ethusa cynapium,* or fool's parsley.

I have been at some pains to compare a thesis, written by Dr. Read, of Ohio, who graduated at the Medical College of Ohio, in 1832, with another thesis, written by Dr. Simpson, of Kentucky, who graduated at Transylvania University, in

1839. Both treat of *milk sickness*, and although entirely unknown to each other, their statements, professedly drawn from personal experience and actual observation, very closely agree. Both assign the deleterious agent in milk to some vegetable consumed by the cows, in *new* lands; and they testify that the effect fails when the lands have long been under cultivation. This statement accords with the great mass of evidence throughout the world, where the phenomena have been noticed. Dr. Simpson and others object to the *miasmatic doctrine*, contended for by some, in accounting for milk sickness, because, as they allege, if cattle be placed on two distant fields on the same farm, the one subject to cultivation for several years, the other in a wild state, and full of native vegetation, those in the latter will be sickened, while those in the former will retain their accustomed health, although both be precisely alike as to the influence of the usual sources of miasmatic exhalations.

In 1833, two citizens of Kentucky came to Cincinnati, anxiously seeking the cause of a terrible devastation among cattle, and human beings, in their neighborhood, which they supposed could be detected in the water, of which the animals and others drank. They handed me a jug full of the water, which was perfectly limpid, insipid, inodorous, and without sediment. The disease complained of was the *milk sickness*, and the water was imagined to be poisoned with arsenic, in some way or other. Yet, it was not possible to detect any sort of poisonous matter; in fact, the water was of the purest kind. I gave it as my opinion then, and still believe, that the milk had been deteriorated by some unknown and not discoverable agent, belonging to the vegetable kingdom. When I say "not discoverable," I refer to the action of tests, for I fondly hope that the source of this poison is yet to be ascertained.

Cheese.—For many years it has been known that cheese, owing to some unusual quality, exerted occasionally a poisonous influence. In the German journals, may be found several very interesting papers on this subject, and they go to confirm the statements so often made in this country, on the same point.

It has happened, that, of a whole cask of cheese received from a given cheesemonger, only one has evinced any poisonous properties, and that had no obvious peculiarity about it, in color, consistence or taste.

The symptoms develope themselves according to the quantity eaten, commencing in from 10 to 15 hours, but deferred, now and then, to a more remote period after the noxious meal. The first notes of distress are, pain in the stomach, vomiting, purging, and dryness of the mouth and nose. The eyes, eyelids and pupils become fixed and motionless; the voice grows hoarse, or fails entirely; the power of swallowing is impaired, the pulse gradually flags, swoonings occur, and the skin is cold and insensible. The secretions and excretions, excepting the urine, are suspended, but sometimes there is a profuse diarrhœa. The appetite is not affected, there is little or no fever, and the mind is unclouded. Fatal cases end with convulsions and laborious breathing, as early as the third, and as late as the eighth day. If the patient recover, he feels badly for weeks, and sometimes never regains his wonted vigor.

The symptoms mark this substance, as belonging to the *irritant* poisons, although, secondarily, it would seem to merit a place among the *narcotico-acrids*.

The *morbid appearances* are, inflammation of the mucous membrane of the stomach and bowels, whiteness and dryness of the throat, flaccidity of the heart, and a strong tendency to resist putrefaction.

That cheese is sometimes poisoned with red lead, that is present in the annato employed to color it, cannot be doubted. Mr. Wright has furnished a good paper on this subject in the Repository of Arts, vol. 8th, page 262. It presents undoubted proof of the poisonous action of some fine looking Gloucester cheese, in which the red oxide of lead was easily detected, by a neighboring chemist. Samples of the annato employed as a coloring for the cheese, were found to be strongly impregnated with the lead. This very dangerous sophistication can be readily detected, by macerating a portion of the suspected cheese in water impregnated with sulphureted hydrogen gas, acidulated with muriatic acid. A brown or blackish color is instantly struck, if the minutest portion of lead be present.

But the most embarrassing cases of cheese poisoning are those in which the ordinary tests fail to discover any evidence of poisonous adulteration. These are of frequent occurrence. About 12 years ago, a large number of persons sickened, after eating of a fine looking and well tasted cheese, which was one of a cask, more than half of which had been sold in the same village. There was no fatal case, but some persons were made extremely sick and suffered great gastric and intestinal distress. I was requested to make an examination of the cheese, and portions were sent to others, for the same object. After a careful research, no poison could be detected by the ordinary means, and we came to the conclusion, that the source of the evil must have been derived from some vegetable matter, eaten by the cows.

The inquiries of Serturner and others go to make it probable, that the poisonous property of cheese often depends on two animal acids, analogous to, if not identical with the caseic and sebacic acids, which we know to be, chiefly, the source of evil in poisonous sausages. It is certain that caseic acid, obtained from cheese, will destroy the smaller animals very promptly, and that the sebacic is even more rapidly fatal.

I feel confident that not a little of the cheese that induces poisonous effects, owes its pernicious quality to the same, or to a similar vegetable matter, that is generally regarded as the cause of *milk sickness*, in new countries. If the milk and the cow that yields it, may be poisoned, as they certainly are, what can prevent butter and cheese made from such milk, from sharing in the evil?

Fatty matters.—By some process, not by any means understood, certain animal matters are so changed, although their exterior may appear as usual, that the eating of them gives rise to very distressing symptoms, and sometimes causes death. Some have supposed, that there is carried on, silently and imperceptibly, a modified putrefaction, which changes the quality, without affecting the form or apparent condition. The articles, most usually altered in this or in some other way, are *sausages, lard, pork* or *bacon*, and *butter*.

The *poison of sausages* has become so notorious, in some parts of Europe, as to have been the subject of a thesis, a prize essay, and other papers. In the Wirtemberg territories, in Germany, we are assured that 234 cases of this kind of poisoning occurred in about 34 years; of which number, 110 proved fatal. In the winter and spring of 1834, similar cases occurred in the neighborhood of the Black Forest, in the territories above named. The symptoms are reported to have been very alarming, and several individuals died. The food eaten by these persons was the sausage of the country, and liver puddings. The former were reduced to a pulp in the centre, were very bitter and rancid, and smelled like cheese. The puddings had been evidently decomposed, as they were quite sour. The remedies found most successful in these cases, were immediate vomiting, a purgative draught of Glauber's salt, and clysters of vinegar and soap.

It is stated by various writers, that the symptoms of sausage-poisoning do not begin until twenty-four hours after the noxious meal has been taken. This is said to be owing to the great indigestibility of the fatty matter, which enters the food. Pain in the stomach, vomiting, purging, dryness of the mouth and nose, are usually the first symptoms. The eyes and eyelids, and next the puplis become fixed and motionless; the voice fails or is entirely lost; deglutition is difficult; the pulse gradually sinks, frequent swoonings come on, and the skin becomes cold and insensible. The bowels are sometimes torpid, at others the very reverse. The appetite is not impaired; there is little or no fever, and the mind maintains its usual tone. Fatal cases end with convulsions and great difficulty of respiration, between the third and eighth days. Such is the shock imparted to the system that even in successfully treated cases, the effects are felt for years.

The *morbid appearances*, in the dead body, are inflammation of the mucous membrance of the stomach and bowels, whiteness and dryness of the throat, thickening of the gullet, croupy deposition in the windpipe, great flaccidity of the heart, and a morbid tendency to resist putrefaction.

What is the nature of the change effected in the sausage, no one has been able to reveal. It has been asserted, that the poisonous principle resides in a fatty acid, called by *Buckner* the *Botulinic* acid. Experiments with this acid, as obtained from the spoiled or poisonous sausage, showed the same results as are witnessed in animals that partake of the sausage itself.

In regard to the poisonous quality of *lard*, under peculiar circumstances, we have little to say, that is satisfactory. Mere rancidity does not seriously affect it. Keeping it in copper or cedar vessels, may render it more or less deleterious.

In the winter of 1838-9. I saw a portion of lard, sent to Professor Peter, for examination, in consequence of having sickened those who partook of it, in any shape. Some were affected pretty severely, though no one died. The lard looked as well as usual, and had no particular smell nor taste. The examination failed to detect any thing of a poisonous nature. It is quite possible, that lard may be poisoned by the empyreumatic oil, resulting from the application of a strong heat to a small portion of it. It is known that this oil, as produced by the destructive distillation of lard, is decidedly poisonous. Five drops, passed into the throat of a bird, nearly killed it.

Pork, in the fresh, as well as the cured state, under the name of *ham*, *bacon*, &c., has often evinced poisonous properties. I am of opinion, that some of the cases of poisoning, as they are termed, by fresh pork, were dependent on other causes. In the summer season, when green or ripe fruit is freely indulged in, almost any kind of fresh meat, not well seasoned, will derange the digestive apparatus, and it has frequently occurred, that true and fatal cholera morbus has resulted from such imprudence.

In the *Philadelphia Medical Examiner*, for Jan. 1839, we have a short paper headed, "poisoning from *pork*," furnished by a physician of Illinois. The patient died, it is true; but he had been laboring for months under gastro-enteritis, was frequently attacked with colic, and often much disturbed by any sort of food that did not suit his condition. Under these circumstances, fresh pork was freely eaten, and soon after, a quantity of grapes, and the man died in nine hours after the commencement of the attack, which did not begin until the day after the pork meal.

I will not say, however, that young pork may not acquire a *poisonous* quality, and kill, as the consequence; but the cases that I have met with, are not satisfactory.

In reference to ham, and all kinds of bacon, the evidence of occasional poisoning is conclusive. This may be the result of very different causes. The meat may be poisoned, in the act of smoking it, as is known to have happened to certain soldiers in Corsica, who smoked their meat with mezereon and other woods. In the careless manner of gathering rubbish for this purpose, many poisonous articles may be accumulated, and the meat may thus be effectually poisoned.

The more common source of poisoning in bacon, however, is doubtless the same fatty acid that renders sausages so deleterious, in some vicinities, and in certain seasons.

The history of a family poisoned by eating a ham-pie, made at a Parisian pastry-cook shop, is deeply interesting. The examinations, made by *Ollivier* and *Barruel*, to detect some kind of metallic poison, totally failed, and the able chemists were forced to the conclusion, that the meat had experienced a change similar to that which gives a poisonous quality to German sausages and ham.

In three hours after dining on the ham-pie, the master of the house was seized with general uneasiness, cold sweats, shivering, violent gastric pains, frequent vomiting, burning thirst, extreme tenderness of the abdomen, profuse purging and very violent colic. The poison was evidently of the *irritant* class, as the same symptoms attacked a daughter aged twenty-seven, and another aged nine. The physician who was called in supposed that verdigris, or some other salt of copper had been communicated, by the pastry-cook's copper moulds. By a vigorous course of treatment the patients recovered. The plan pursued is not stated. It should be borne in mind, however, as a reason for suspecting a copper poison, that the alvine discharges were as green as the common house leek.

Dr. Geisler has given, in *Horn's Archives* for 1828, the account of a family of eight persons,

evidently poisoned by bacon. Their symptoms, with the addition of delirium and loss of recollection, were the same with those resulting from the sausage poison. A remarkable circumstance in this history is, that the father escaped unhurt, "having stewed his bacon, while the rest ate it raw." It is supposed, that the process of stewing dissipated or decomposed the fatty acid, so as to render it harmless.

In the London Medical Gazette, vol. 19, 378, we have the case of a family poisoned by bacon, or rather, several members of the family. All who partook of the meat were sickened, and one of the children died, after severe gastric and intestinal distress, which continued for more than three weeks. Severe spasms and violent retching with dreadful headache were the attendant symptoms. *Post mortem* examination revealed extensive gastric ulceration.

The difficulty of deciding, satisfactorily, as to the true source of poisoning, in animal matters, has been alluded to. We may remark, further, that many families have been sickened and some persons fatally poisoned, by eating the meat, variously cooked, of animals that had sickened and died. The symptoms in these cases, are those of *irritant* poisoning, such as gastric pains, vomiting, severe colic, diarrhœa, &c., &c. In all these cases, it is quite probable, that the fatty matter of the animal experiences a change such as occurs in the German sausages, though this is only a conjecture. It would seem that the proper course of treatment would be to dislodge the meat from the stomach, and then to allay the irritation, by means of anodynes and rubefacients, blisters, &c., to the epigastric region.

The fatal poisoning from a wound inflicted by the dissecting knife, is too well known to require any detailed notice here. That such wounds are not always injurious is certain; and we are at liberty to suppose, that when they do prove alarming and fatal, it is in consequence of the change already named, in the fatty matter of the dead body.

In view of all the facts above stated, in reference to the poisonous agency of animal matters, may we not very rationally extend our future researches in the following queries, in the hope of reaching the truth at last?

1st. Is it not probable, that the fatal effects attending the use of the meat, milk, butter, cheese &c. of cows, as well as of the flesh of other animals, may depend on the noxious influence of *many* articles in the vegetable kingdom?

2d. Is it not probable, that *some* cases of milk-sickness, as well as the disastrous train of symptoms that follow the use of various animal matters, as articles of food, may be fairly ascribed (conformably to Orfila's suggestion) to *new principles formed or developed in the living animal, by a vital process*, and wholly independent of the pernicious agency of *any* vegetable matter?

Perhaps some of your readers may think there is no sort of relation between the several facts contained in this article. On this point I beg to differ; and hoping that some good may result from their perusal, I submit them to the intelligence and good sense of all candid inquirers.

AN ESSAY ON THE MAKING, THE PRESERVING AND THE APPLYING OF MANURES.

For the Farmers' Register.

This subject, as the caption indicates, is divided into three parts: 1st, the making; 2d, the preserving, and 3d, the applying of manures; and I shall treat the subject according to the above division. And here it is obvious to remark, that this subject is to the farmer one of primary importance; for in this section of country our lands are naturally very poor, or by long cultivation have become completely exhausted. It is therefore a question of the gravest importance, how we can most economically, and at the same time most certainly, impart that fertility to our lands, which will make them capable of producing large and profitable crops.

This subject, at this time, derives an additional importance from the fact that, owing to the exceedingly deranged state of our currency, the high rate of exchange to which we have to submit, the consequent depressed state of the market, and the extravagant and constantly increasing taxation which is imposed upon us, for the support of legislation—our salvation, and indeed our very solvency as farmers, depends upon the *large amount* of produce we can throw into the market. The time has been, as many of us well recollect, when a barrel of corn would bring $10, or a bushel of wheat $2.50, or a hogshead of tobacco would bring $250, and in some instances a still higher rate. Now, although I am no advocate for inflated prices such as these, yet it is obvious that a reaction has taken place, which has produced a state of depression still more injurious; for if the farmer can *now* get one third, or even one fourth as much for the same articles, he considers himself as having made a good sale. Our farmers are at present in this strange situation, a situation which operates with peculiar oppression upon them, that whilst their expenses with the blacksmith, with the shoemaker and grocer, and for labor, generally remain the same, and in some instances are even enhanced, nearly or quite all the products of his farm are at a slow sale, and at greatly depressed prices. The only remedy in this case is greatly to increase the amount of disposable products. Instead of *one* hogshead of tobacco, or *one* barrel of corn, or *one* bushel of wheat, we must have at least *three;* and even then our net income, compared with former times, will be greatly curtailed.

And now the question is, how are we to secure this greatly increased product? It is evident that our lands, in their present poor and exhausted state, cannot supply it. The only alternative then is to enrich the lands, if we would increase their product. And here I will remark, that bad as the times are, I have no idea of "giving up the ship," for I do know, from actual experiment, that by a judicious course of manuring and cultivation, it is practicable to increase the product of our lands some three or even four-fold. Of all mothers, Mother Earth is the most generous; the more liberal we are to her, the more liberal she will be to us.

Having made these preliminary remarks, I proceed at once to the first branch of my subject—the best method of making manures. And here I intend to confine myself to the actual circumstances of that section of country in which the

great majority of our Agricultural Society reside. In some portions of our state, large and even inexhaustible quantities of marl and lime may be commanded at comparatively little expense. Here then the very best manure is at once furnished to the industrious husbandman. But as comparatively little of these articles has as yet been found in our county, I shall say nothing as to their preparation or application. Indeed the subject, as presented, was intended to embrace, not the *calcareous*, but the *putrescent* manures.

I would observe, then, that the great basis of this article is vegetable matter. This matter, when reduced to a state of decay, is manure, but the quality may be greatly improved, and the quantity greatly increased, by a proper mixture of animal excrement. Stock then, of some kind, if not essential, is highly necessary to the making of manures. The whole subject then resolves itself into this one thing—how are we to employ our stock, so as to make them most available in this important particular? Of animals, there are three classes in common use among us—the horse or mule, the cow, and the hog. As to the first, I suppose there is but one opinion among us, and that is, that when not employed, he ought to be confined to his stable, and there plentifully supplied with litter of some kind. How long this litter ought to accumulate before it is removed, is a matter of some doubt. Some are in the habit of removing it every morning; but after paying considerable attention to the subject, I am of the opinion that it ought to remain, until by its great heat it endangers the health of the animal. It is a fact well ascertained, that decomposition goes on much more rapidly in large than in small masses. The best plan, therefore, is to keep the stable clean, not by throwing out the old mass, but by putting in frequent supplies of fresh litter. That which is already undergoing decay, will greatly expedite the decomposition of the fresh supplies. But as during this process not only great heat is evolved, but also a large amount of gases is thrown off, there is great danger of allowing this thing to proceed too far. Every farmer ought therefore to pay special attention to the condition of his stable, and when the heat becomes excessive, or when on opening the doors the slightest degree of offensive effluvia salutes him, he ought forthwith to remove the whole. My plan has heretofore been (and I am more and more pleased with it) not to throw it out in a mass, and there allow it to fire-fang, or to be torn to pieces by the hogs, but to carry it directly to the field, where it is spread, or to deposite it in small quantities, ready for future use. Fresh litter then is put into the stable to a large amount, and thus a foundation is laid for another supply.

Two methods have been successfully practised to make *cattle* useful in supplying manure. The first is to confine them to their stalls, in which case the same process is to be employed as with the horse or mule; or, 2dly, to let them have the general use of the farm pen, restricting them to their stalls only in bad weather. The latter, especially where the farm pen is kept well littered, I think the preferable mode: for on this plan, much time is saved in feeding, it being much easier to scatter the food over the farm pen, from which each one takes his portion promiscuously, than to place it in each separate stall. After taking their food they either remain in the farm pen, where their droppings are left, or if the weather be bad, they retire to their shelter and deposite them there. Here also great cleanliness ought to be observed, which can easily be secured by frequent supplies of fresh litter. Nor let any one grudge the time and care of this apparently troublesome process; for the more litter he furnishes, the more manure he will have for his exhausted fields.

There is also a third method of employing cattle in the enriching of land, of which I think very favorably, and that is by confining them to a small portion of land, until this is properly enriched, and then removing them to another portion. This is done with considerable convenience, by means of what are commonly called moveable pens. The size of the enclosure will of course depend upon the number of the cattle, and the length of time it is intended to keep them on one spot. By this expedient, especially where the number of cattle is great, a large quantity of land may be greatly improved every year. And it is done with this great convenience also, that all the labor of carting out the manure to the field, and then of spreading it, is saved. But it ought to be observed, that on this plan the land ought to be ploughed *before*, and some say *after*, it is manured. In the latter, however, I do not agree with them.

But there is another animal, the value of which has been heretofore greatly overlooked, and therefore greatly neglected, which, if properly treated, will show himself not inferior to any other in the great business of manufacturing manure, and that is the hog. In England, where this great concern is attended to with an economy and success, altogether unknown among us, each hog is taxed with ten loads of manure every year; and when he is treated properly, and is furnished with suitable materials in sufficient quantities, he invariably acquits himself as a clever fellow. But on this point I must be a little more particular. I would, then, confine my hogs in small pens, say 10 feet by 8, with a floor sloping considerably to the front. In rear of this should be another pen, say 8 by 6, well sheltered, to which the hogs might have free access in bad weather, as also for sleeping. This will afford accommodations for five or six hogs. In the front or larger pen, besides the trough for water, I would put large quantities of litter. In addition to this, I would furnish regular supplies of dirt, taken from the scrapings of roads, ditches, &c., or of rich deposites of mud collected from marshes and other low places, and, as still better than this, all the ashes I could command, and over the whole strew corn as food for the creatures. And now would commence their work in good earnest. That snout of theirs, which to my fields and ditch banks is such an annoyance, would here display itself to my immense advantage. In a very short time, they would thoroughly mix and incorporate this whole mass, so that new accessions of similar materials would be necessary. When this is the case, put in fresh supplies, and thus continue till the mass becomes inconveniently great, then remove the whole, and begin the process anew. If, upon cleaning out, the litter is sufficiently rotted, carry it directly to the field; if not, (and this is frequently the case,) let it be heaped up, in which state it undergoes a slow decomposition, and in time will be fit for removal. In this way the 5 or 6 hogs will make from 50 to 60 loads

of manure during the year. According to this, a hundred hogs (and many farmers keep that number, or even more) will make a thousand loads, and this is enough to enrich twenty acres of poor land, or to keep forty in a state of continual improvement.

I have now finished what I had to say as to the stable, the cattle shelters, and the hog-pens, as so many sources of manure. But there is another resource which, in a treatise of this kind, ought not by any means to be overlooked, and that is the farm pen. It will be conceded, that no farm can be properly conducted, without this indispensable appendage. As to the *location* of the farm pen, all will agree that it ought to be situated immediately adjoining the barns, the stables, the cattle shelters, and such other buildings as we use for storing away our winter supplies of food. Here the cattle are fed, and here we deposite the corn stalks, and wheat straw, and damaged provender, and weeds, and litter from the woods, and such other materials as we wish the cattle to tread down and to convert into manure. This is in fact the great depot of all the raw materials, which we intend to work up in the great manure workshop. But if we would conduct the concern with efficiency, we must keep a plentiful supply of materials on hand; and if with these we mix small quantities of lime, or larger quantities of wood ashes, or even of coal ashes, the quality of the manures will be greatly improved.

As yet, I have said nothing as to what is commonly called the *liquid* manures of our stock. In older countries, where the population is very dense, and where every foot of tillable land is necessary to raise the food needed by the people, and where, of course, they cannot command, from the woods and the fields, the quantities of litter which we can, there great care is taken to collect and preserve all the liquids of their stock. For this purpose their stables, both for horses and cattle, are furnished with cisterns or tanks, into which all the liquids are carefully drained; and after they have undergone the necessary putrefaction, are pumped out, and sprinkled over the crops, and great benefit is said to result from the application. But in this country, where population is lamentably thin, and woods and weeds are lamentably plenty, and large supplies of litter are always at command, I do doubt if a discreet economy would warrant the expense and trouble of collecting and applying the liquid manures. And my doubt is founded in this, that just in proportion as we increase the *liquids*, we diminish the *solids*. My theory is, that the liquids are quite as necessary, and even more so, in exciting and hastening the decomposition of the litter, than the solids are. If therefore we drain away the liquids, we arrest or at least retard the decomposition of the litter, and therefore a less quantity of manure is made. No one, I hope, will understand me as detracting from the value of liquid manures. My plan is to furnish a sufficiency of litter to absorb the whole. The liquids therefore are not only secured, but they display their great efficacy by rapidly converting the large quantities of litter into a valuable manure.

But as the term *litter* occurs very frequently in this treatise, perhaps I ought to explain precisely what I mean by it. It is, first, the corn stalks, which ought to be cut down as early as possible, and deposited upon the farm pen, and thereby passing the carts and wagons over them, and the trampling of the cattle, and the rooting of the hogs, they are broken down and made fine; so that by the next spring a considerable portion of them, perhaps half, are in a condition to remove from the top. These are carried to the corn field, and when properly managed are a great aid in the subsequent crop. The balance are left till the fall, when the most of them are sufficiently decomposed to top-dress the grass lands with. Besides this resource for litter, the fields which produced small grain, if in good heart, and none others are worth cultivating, will be found, early in the fall, well covered with a large crop of the wild carrot and other weeds, intermixed with young clover and other grasses. These ought all to be mowed down, and carefully stowed away as litter for the stable and hog pens, and I know of no material of which a richer and better manure may be made. And then they who cultivate grass on a large scale know that portions of their fields, particularly along ditch banks, and low sunken places, and corners of fences, are much infested with weeds and briers and coarse grass, such as will not make merchantable hay; these ought all to be taken care of in the same manner and for the same purpose. And then last, "though not least," leaves from the woods. When all these sources are carefully husbanded, every one must see, that an immense amount of valuable material will be stored away for the manure pile. Indeed I will venture to affirm that, as a general thing, not one farmer in twenty avails himself of the abundant supplies which he has at his command, to enlarge the stock of his manures. And as long as this continues to be the case, our land must necessarily remain poor and unproductive. For my part, I would leave the song of "*hard times*," to be sung by the merchants and other traders alone. It is a chant which very illy befits the mouth of the farmer. He, with his rich land, and habits of economy and industry at home, is an independent man. Whilst, therefore, others harp upon the ruinous exchanges, the scarcity of money, and the villany of the banks, let the farmer look well to his manure pile. Above all, let him feel that his great business is to add to the fertility of his land *every day*. Then, when others yield to the pressure of the times and become insolvent, he, with no money deposited to his credit in the banks, but with his fat hogs, his full corn crib, and his barns well stored with all kinds of provender, will remain firm amid the general wreck.

I close what I have to say on this branch of the subject, with one remark, and that is, that the quantity as well as the quality of manure will be materially affected by the quantity and quality of the food which we give to our stock. If we dole out poor food to them in limited and stinted supplies, the returns in the way of manure will be of the same character. Whereas, if we supply them with generous food and with a liberal hand, the returns will be of the same nature.

2dly. The next thing to be considered is the best mode of preserving manure. This is also a very important part of the subject; for it is surely very bad policy, to waste or destroy that which is so valuable to us, and which it has cost us so much time and labor to obtain. We should justly consider that man a maniac, who would wantonly

throw away his purse well stored with silver or gold, a case, by-the-by, which *could* occur with but very few now-a-days. Equally foolish would that man be, who would suffer his manure, the strength of his land, and the very basis of his wealth, to perish for want of proper preservation. And here I would remark, that the great enemy to be guarded against is inattention and indolence. As a general rule, manures ought always to be used, or at least placed in a situation to be used, as soon as they are thoroughly made. Manures consist of vegetable and animal matters variously combined, in a state of decay, which, in consequence of the decomposition in actual progress, are constantly evolving certain rich and nutritious gases, and these gases, if not imbibed by other living vegetables, are constantly escaping in the air. The manner in which manures benefit the growing crop, whether by entering into it in their solid state, or whether they are first decomposed into their original elements, these elements enter into it, I shall not now undertake to determine. It is sufficient for me to know that manures, as soon as fairly made, begin to waste away. Here then is a loss; nor is this loss occasioned merely by what is commonly called evaporation. It is greatly accelerated, if not principally caused, by what may be properly called a *combustion*. To satisfy any one of this, let him put a small quantity of manure in a heap, a single cart load is sufficient for the experiment, and in 48 hours or less he will see a dense vapor issuing from it, and on digging to the centre, will find that a great heat has been generated, so that a real combustion, commonly called *fire-fang*, has actually commenced. Now it is obvious, that unless this destructive process is arrested, a considerable portion of the solids will not only be burned up, but in this process we shall lose a large share of the nutritious gases also. The best preventive that I know of for this waste, is to remove the manures to the field as soon as fairly made, and then spread forthwith, or if inexpedient to spread, to place in small heaps, not exceeding 5 or 6 bushels to each. Some farmers are exceedingly afraid that their manures will sink down into the ground, and thus become inactive. I will cheerfully incur this risk, provided you give me a guaranty that they will not rise up, and be dissipated in the atmosphere. The whole secret, therefore, as to the preservation of manures, resolves itself into this one thing, to mark when they are thoroughly made, and then immediately to use them, or, at least, to place them in a situation for future use. And the longer this thing is delayed, the less manure you will have, and of course the greater loss you will sustain.

The third and last thing to be treated of is the best mode of applying manures. There are, as far as I know, but two theories on this subject; and each theory has its strong and decided advocates. The first is to use it as a top dressing; the other is to spread and immediately cover with the plough. After a long and close observation on this subject, I have come to the conclusion, that each mode, according to the circumstances of the case, is the correct one. If the manure be fine and fully made, then I hesitate not to say that the most judicious mode of application is in the way of a top dressing. If on the other hand it is coarse and but partially made, then it ought to be covered with the plough. And my reason for this course is, that the finer and well made, manures *being now in a state to act availably*, I wish to continue in that state as long as possible; whereas, I wish to change the state of the coarser, by subjecting it to as rapid a decomposition as I can effect. If, therefore, I have the coarser on the surface, it will but bleach in the sun; but if I cover it to a small depth, it will imbibe moisture, and, as it rots, impart its nutritious properties to the growing crops. On this plan, I permanently secure that which is fully made, *in its present state;* whilst, by covering, I subject the other to a continued decomposition, and thus bring it into an available state also.

The main argument by which the advocate of the covering system supports his theory is, that manures, when left on the surface, are continually subject to evaporation, and therefore lose their valuable gases and other fluids. Now what are these gases? Every chemist will tell you, and that upon actual experiment, that they are fluids, so subtle, so elastic, that it is almost impossible to confine them. This being the case, can any suppose that they can be confined by a covering of loose porous earth, such as land always is when fresh ploughed? These subtle substances —if I may be allowed the expression—would laugh at a confinement of this sort. No! the chemist can scarcely confine them in his retorts, prepared with the greatest skill. In vain then will you attempt to confine them by a slight covering of loose earth. But suffer me further to inquire, what is the *object* of confining them? Is it, that when thus covered up, they may enter into the plant by means of its roots, and thus nourish it? But it is a fact, admitted as such by every body, that the roots are not the only appendages of the plant by which it receives its nourishment. The *leaves* are essential to the plant in this respect. Hence, if you destroy the foliage of the plant, it sickens and dies; and hence caterpillars and other worms are so destructive to fruit trees. The leaf then is intended to perform certain primary functions, connected with the health and thrift of the plant. For this purpose it is furnished with two surfaces, by which, it is said, it performs certain offices very similar to respiration in the animal creation. By one, it receives the gases, and by the other, it throws them off, when they have been sufficiently elaborated. It appears, therefore, that we should but partially do our work, were it in our power, to place these fluids in a state to be taken up by the roots alone; the *leaves* require their portion, and this is indispensably necessary to the healthful thrift of the plant. My theory is simply this, that between the plant and its several parts, and these various gases, there is a strong affinity: when therefore the attraction to the root is strongest, the gases go there, and when the attraction to the leaf is strongest, the gases go there, and this is the case, whether the manures be left on the surface or covered up. In the one case, they descend to the root, in the other they rise up to the leaf, and the peculiar position in which you place them makes very little difference, for their great fluidity prepares them for the change. I have already stated that the great object is to preserve the finer manures as long as possible in their present state. Being now available, the great object is to con-

tinue them as they now are. And now the whole question is narrowed down to this single point, in which state are manures most susceptible of preservation, when left on the surface, or when partially covered? On this subject, I suppose, there can be no division of sentiment. Every one will agree, that vegetation undergoes a much more rapid decay when covered than when uncovered. In accordance with this, every farmer ploughs in his green crops, or dry crops either, when he wishes them to undergo a speedy decomposition. I conclude, therefore, that surface applications of manure are to be preferred.

COCKROACHES.

From the American Farmer, for 1827.

Having seen a plan proposed some time since, in the Farmer, for driving the cockroach from books, furniture, &c., by the use of spirits of turpentine, for the benefit of those infested with them, I propose the following plan, the success of which I have fully tested. Take an ounce vial and put in sweet oil or soap-suds, to the depth of an inch, and set the vial against the books, shelves, or places infested, so as to facilitate their getting in. They will readily go into the vial, and are unable to return, as the oil or suds renders it impossible for them to climb up the sides of the vial. I tried this plan in a closet very much infested, and in a few weeks the vial was filled within an inch of the neck. I emptied it, and in a few days there was not one to be found in the closet. If you consider this worthy of publication, it is at your service.

ON LIME AS MANURE, AND CALCAREOUS FORMATIONS OF THE MOUNTAIN REGION.

[The remarks and inquiries addressed to us by one of the most intelligent and successful improvers of land in western Virginia, concerning the calcareous tufa of the limestone streams and other calcareous substances of the mountain region, have induced the republication of the following letter, which presents views that we long ago took up on that head, and which we have since had no cause to alter, nor means to test, by further observations.—Ed. F. R.]

From the Winchester Republican.

Agricultural Society of the Valley—May 29, 1826.

A letter from Wm. B. Page, esq. enclosing a communication from E. Ruffin, esq. was received, and the communication from Mr. Ruffin ordered to be printed.

Coggin's Point, October 20, 1825.

Dear sir,—Your letter reached me only a few days before the commencement of a long journey, which has prevented my attending to your request until this time. I shall now endeavor to answer your inquiries as fully as my limited means will permit; though I cannot expect to furnish any thing of more value than loose hints, which perhaps may serve as subjects for a Frederick farmer to think about, but not as rules to direct his practice.

It should be observed, that though I have applied *mild lime* to more than 500 acres, scarcely any use has been made by me of *caustic* or *quick lime;* and therefore I have no practical knowledge of its peculiar solvent power. According to the theory of Davy, while lime continues caustic, it acts powerfully on all animal and vegetable matters in contact with it—breaking down and rotting whatever is hard, insoluble and inert—and driving off or destroying whatever is already rotten, or fit for the immediate use of growing plants. Hence, we may infer that the mere causticity of lime will be serviceable or hurtful, according to the state of the vegetable ingredients of the soil. But as usually applied, quick lime becomes as mild as before burning, by again absorbing carbonic acid from the atmosphere, before its solvent power can be exerted. Nor do I think this power can safely be used in our climate, except in very few cases; as on broom-straw old fields, or newly cleared poor woodland, which contain much inert, and but little active or soluble vegetable matter. Under our hot summers, vegetable manures rot too fast, and the cultivator should endeavor to retard, rather than hasten their decomposition. But a different practice may be proper in colder climates. Frequent applications of caustic lime must be highly useful in Scotland, for example, where vegetable matters, unrotted and insoluble, have continued to accumulate and extend, until one sixth of that country is covered with barren peat.

It follows, then, that however powerful may be the effects of caustic lime, they must be considered as separate and distinct from the durable and far more valuable effects of mild lime, or calcareous manures in general. The same substance, (quick lime) will at different periods act as two kinds of manure, entirely different in their modes of operation; and, on the other hand, many substances having different names, (as old burnt lime, chalk, shells, limestone, leached ashes, and marl,) all have different proportions of the same calcareous ingredient, and ought to be considered as the same manure. Yet most writers class these manures under different heads, without knowing the sameness of their predominating qualities; and many absurd practices owe their origin and continuance to the same error in our practical men. Thus the industrious farmers of Long Island have long used, as a manure, leached ashes, brought hundreds of miles by water: they have even sometimes stripped the soap factories in Petersburg, paying five or eight cents the bushel, besides the expense of so long a transportation. Yet, whatever benefit was obtained from this manure, they might have found as well in the fossil shells which I believe lie beneath the surface of all Long Island, and which, even if carried the same distance, might be applied at less than half the cost of an equal value of ashes. Your remarks show that we agree in this view—and that you correctly consider our calcareous manures as substantially the same, though your practice may be confined to calcined limestone, as mine has been to fossil shells.

I now proceed to answer your particular inquiries. You ask my "opinion as to the utility of lime as a manure in general; to what crops and

in what mode it is most advantageously applied; and whether there is reason to believe that it would be adapted to limestone soil like ours, originally rich, but in many places much worn by cultivation?" I never was in Frederick, and know but little of its soils, except that they generally differ from those on which my practice has been tried, and with which I am best acquainted. Your own judgment can best determine when any practice which may be profitable here, will also be advisable in your situation; and for that purpose, it will be necessary for me to state concisely my view of the means by which lime acts, and the different effects produced, referring you for the reasons on which they rest to my essay in vol. 3, American Farmer.

The principal action of both sand and clay is mechanical, and therefore large proportions are required to produce perceptible effects as manures. But from the presence or absence of a very small proportion of lime in soils, important results are produced, because in common cases lime acts chemically, and not mechanically. Clay has but little power, and sand none, in holding vegetable or animal manures: but lime combines with them strongly, fixes them in the soil, and yields them solely to the growing crop. Hence, without lime, no soil can be long otherwise than barren. Though most soils are more or less deficient, none capable of supporting vegetation can be entirely destitute of lime in *some* form. This property of lime, of combining with and fixing manures, may be advantageously used on every soil which nature has not made abundantly calcareous: but this benefit must necessarily be gradual, never quickly perceptible, nor can it be expected at all, unless on soils under meliorating culture, which will allow more to return to the earth than is taken off.

The next most important effect of lime is that of neutralizing acids. Lime is never furnished by nature pure, as it attracts acids so strongly as always to be combined with some one or other—and most generally with *carbonic*, the weakest and most abundant of all, and with it forms *mild lime*, or *calcareous earth*. This acid is driven off by strong heat, leaving the lime then pure, (or caustic,) or it will readily yield its place to any stronger acid which may be brought in contact. Thus, if a bit of chalk or limestone be thrown into diluted *aqua fortis*, the strong acid seizes on the lime, the weaker escapes in air bubbles, and (if enough lime is used) the acidity and other qualities of the aqua fortis are entirely destroyed. Such a process takes place in most of our soils when lime is applied, and probably may in some of yours. Decaying vegetables or other causes produce acids, which either combine with lime and form useful manures, or if all the lime has been already taken up, poison both crop and land. The mark of an acid soil is a vigorous growth of pine, whortleberry or sheep-sorrel. When enough lime (whether mild or caustic) is applied to a soil of this kind, the poisonous acid is destroyed, one cause of barrenness removed, and the first crop may be increased from 50 to even 200 per cent. before any other effect of lime comes into action.

There are several other minor benefits from lime, with a detail of which I shall not trouble you; for if my opinions are well founded, the two properties of fixing manures and neutralizing acids are sufficient to show that lime (and nothing else but lime) will enable us to make durable and profitable improvements on such soils as are naturally poor.

Since the publication of my early experience of marl, (as we improperly call the bed of fossil shells,) my opinion has suffered no change or abatement as to the value of that manure. I have extended the improvement over my farm as fast as possible, and generally with great benefit, though sometimes to loss. Not fearing any injury, I applied in most cases from 500 to 800 heaped bushels of shell marl per acre, about one third of which, on an average, was pure calcareous earth —and the crops of the present and preceding year have given proof that I was too lavish in the application. Several of my neighbors found equal injury from smaller dressings, but on land not secured from grazing, or more severely cropped than mine. Where equal quantities were put on, the injury on my land was in proportion to the poverty or sandiness of the soil, or the deficiency of vegetable matter: under opposite circumstances, no injury was produced even where 1000 to 1200 bushels had been laid on. The remedy for this error then is apparent—and where too much mild lime has been given, the soil is made more able to retain and profit by the vegetable matter which is then wanting. No soils have yet suffered in this way except such as were before *acid*, which induces the belief that the *salt of lime* (formed with the vegetable acid) causes this disease—and unless enough dead vegetable matter be present for this salt to act on, that it will injure the growing crop. Though I have lost some crop, and much labor, by these heavy dressings, the result has not discouraged me; it only shows the manure to be much stronger than I thought, and that less will be sufficient to produce either benefit or injury. Candor requires the statement of loss from marling, which however could not have occurred either to my neighbors or myself, if the advice I formerly gave had been attended to, viz.: to apply the manure in small quantities, and repeat it as might be found necessary; and not to use it at all, if exhausting cultivation was to be continued. No first crop after marling has suffered by this disease, (and its marks are too evident to be overlooked;) and when it has occurred in the second rotation, it never reduced the crop so low as the product of the land in its previous state. Another fact is worthy of observation: on spots where wheat of this and last year's crop was almost destroyed by overliming, clover stood and grew so well, that it promises to draw off the excess of the *salt of lime*, or otherwise to furnish enough vegetable matter to balance and cure the evil. Of this, however, my experience is as yet too limited to be considered as furnishing conclusive evidence.

When not diseased, the crops of the second rotation have been always as good, and sometimes much better, than the first crops after the fossil shells were applied. This increase was looked for, and promised, before facts had proved this effect of lime. My later experiments with first dressings give results similar to those already published. But the most satisfactory proof I can offer you of the value of calcareous manures, is a statement of my crops of wheat, which having been generally my only article for sale, and always the most important, as much as possible was raised,

and the average product may fairly be supposed to mark with tolerable accuracy the increase of fertility in the farm.

The last crop I expected would have been at least 2000 bushels, and that it fell short was entirely owing to the unexampled injury caused this season by rust. As it was, my loss was less than on any other farm in the lower country that I have heard of, as but few made half a crop, and many did not save enough for seed. This difference was mostly owing to the manure I had used, as lime hastens the ripening of all crops, and a few days difference in the ripening of a field of wheat may either cause its destruction by rust, or insure its safety.

None of my limed land brought wheat until 1820, and the following table shows that but little average increase of product had taken place before.

Years.	Acres.	Product.	Average.	
1813	145	810	$5\frac{85}{145}$	Average per acre for 3 years—$5\frac{1}{2}$
1814	110	550	5	
1815	78	520	$6\frac{52}{78}$	
1816	104	896	$8\frac{64}{104}$	Second average—8
1817	79	595	$7\frac{42}{79}$	
1818	63	450	$7\frac{9}{63}$	
1819	132	1015	$7\frac{91}{132}$	Third average—$7\frac{1}{2}$
1820	119	1020	$8\frac{68}{119}$	
1821	160	1049	$6\frac{89}{160}$	
1822	154	1627	$10\frac{94}{154}$	Fourth average—$10\frac{1}{2}$
1823	139	1475	$10\frac{85}{139}$	
1824	194	1850	$9\frac{104}{194}$	
1825	195	1452	$7\frac{37}{195}$	

Some of the after increase is certainly due to other kinds of improvement; but I have no doubt that full three-fourths of the whole was caused by the use of calcareous manures, on land rested two years in four, and not grazed. During the first six years, only about half my corn land was put in wheat, the other half being so poor that even our overseers admitted that seed would there be thrown away. You must observe, therefore, that it was the richest half of each shift that averaged from $5\frac{1}{2}$ to 8 bushels. During the last term, all the land before left out, has been in wheat, which makes the increase of average product greater than would appear from the table. Even the highest rate of product above stated, may be thought contemptible by a farmer on your fine wheat lands: but through our poor and sandy country, the average does not exceed 5 bushels for the land actually put under wheat, and it would not be 3, if all the corn land was sowed. Yet the time will arrive, when by means of our calcareous manures, this now barren region, will show the fields the most highly improved above their natural state, and more profitable farming, than any portion of Virginia.

Your doubt whether lime will suit limestone soils, arises from the supposed similar constitution of soil and manure. I have not much personal knowledge of limestone lands, but have always supposed them, as you describe yours, "originally rich," and have attributed that richness to their being manured by nature with lime. It follows, from the supposition, that the value of lime as a manure will be lessened in proportion to the natural supply; that sometimes it may be useless or even hurtful, (as when the soil will effervesce with any strong acid,) and in no case can it be as beneficial as on our pine and whortleberry lands, which are entirely destitute of calcareous earth, and nearly so of lime in any other form. But it does not follow that lime may not be advantageously applied to most limestone soils, though to what extent and profit, experience can only show; for it is a remarkable fact, that but few of those in this state contain any portion of calcareous earth, (*carbonate* of lime,) though they are evidently affected by the limestone with which they are mixed, or in contact with. To the question, what has become of the calcareous earth which the soil must have derived from the rock, I answer, that it still remains in the soil in another form: the lime being combined with the acid furnished by the decomposing vegetable matter, which being abundant enough to take up all the lime applied by nature, shows that more might be beneficially applied. I cultivate more than 100 acres of land, naturally containing a slight mixture of shells, and which, in this respect, as well as in natural fertility, I suppose is nearly similar to your limestone soils; here the effect of calcareous manures, in the first crop, is scarcely perceptible, though I confide in the benefit increasing with time, and accordingly shall marl the remainder of this soil, as soon as I can finish what is less favored by nature, and where greater improvement has been derived. But others have met with more pleasing results. Your friend, Benj. Harrison, found great benefit from fossil shells, which he carried across the river from my shore, and applied to some acres of the naturally rich land at Berkeley. The extensive improvements made with oyster shell lime, by George E. Harrison, at Brandon, are mostly on land naturally rich, and not more destitute of lime than you will find most of your limestone soils.

When I speak of limestone soils, I mean to confine the term to such as are so intermixed with limestone, or lying so near it, that the soil must necessarily have been furnished with some of its component parts from the stone. If my theoretical opinions are correct, every such soil should be naturally rich, durable, and, when worn by cultivation, easy to restore by rest or manure, compared to poor natural soils. If you know any exceptions to this rule, if any real limestone soil is poor (without being made so by such evident causes as wetness, excess of rock, &c.) I would gladly be informed of the facts, as they would furnish the only known contradiction to the opinion before stated, that a proper proportion of calcareous earth will make all soils capable of becoming and continuing rich. But if Frederick is like Augusta and the adjoining counties which I have visited, you have soils enough, which, though (by courtesy) called limestone, are not better entitled to that name than the pine lands of the lower counties. By most persons, the term *limestone* is applied, not only to any land that shows a few detached masses of that rock, but also to wherever there are limestone springs, or under which a body of limestone lies, though forty feet beneath the surface. If the soil could be made calcareous by so distant a substratum, then the whole tide-water district would be so, as a body of fossil

shells lies under the whole extent, and generally much nearer the surface. Much of this land appeared to me very poor, and I think would be as much improved by lime as any of ours.

You ask, "to what crops, or in what mode, is lime most advantageously applied?" My fossil shells produce the most immediate effect when laid on the sod before ploughing, and corn, or some other horse-hoed crop, is first raised, to mix the manure well with the soil. But when convenient, I prefer laying it on after ploughing, as it is better intermixed in the course of cultivation, and the danger of its being buried too deep is avoided. Caustic lime is usually applied to the surface of ploughed land, and slightly covered by repeated harrowings; and it is evident that this mode of covering must convert the quick to mild lime, before its solvent powers can reach the more deeply buried vegetable matter.

Until I began on cotton this year, I have made no field crops except corn and wheat, to which calcareous manures are equally beneficial. Clover is much more improved than either by lime, and without it, (applied by nature or art,) it is in vain to attempt raising clover to any extent, in this part of the state. Several years ago, I formed the opinion, that on land made calcareous, gypsum would act, though of no effect before; and though not confirmed, the opinion has gained strength from my experiments and observations, and however opposed some facts are, the greater weight of evidence is decidedly in its favor. The *acidity* of our soils, I think, will serve to account for the general want of effect from gypsum, and the supposed change of results after first applying lime; but it would be premature to offer the explanation of a fact which, however important it may be, is yet of doubtful existence. You are aware that gypsum has seldom any effect below the falls, and that most of the opposite results are on the rich river lands, of all, the most exposed to the "salt exhalations," which have idly been supposed to cause this remarkable and general defect in our lands. You state the general objection to liming in Frederick to be, first, the belief that your soils are already sufficiently calcareous, and secondly, the cost of fuel. I have before offered you reasons for my belief that your soils generally are not even slightly calcareous, and on the most accurate examination, I do not think you will find a twentieth part of even your limestone soils to contain the smallest proportion of calcareous earth. The expense of burning I cannot estimate even on the practice of neighboring farmers, of whom I have in vain made inquiries. But even if your fuel should be rather more dear than on James river, you would obtain the material for lime at far less cost. Oyster shells, taken from vessels off the landing places, cost 62½ cents per hogshead, (yielding 14 bushels of lime,) while you would quarry the rock on the farm, or perhaps the field, where the lime was to be spread. But I doubt whether burning will be necessary in every case where you may manure with lime; as its solvent power is seldom used or wanted, it will serve as well mild as caustic, if it can be broken down fine enough without heat. Limestone gravel is used to great profit in Ireland, and perhaps may be found in our limestone country; and from my own limited observation, I know that substitutes for it may be obtained in various places, if they should be found to suit as well in their quantity, as in their richness. With a view to answering your inquiries, I paid attention to the subject during my late visit to the mountains, and would have examined many supposed materials for manure, but for the want of the necessary tests; as it was, I brought home, and have analyzed, eight or ten specimens of rock, which from their softness and supposed abundance, seemed to promise calcareous manure of some value, without the cost of burning. Of these, one, frequently seen in the roads, is like limestone in color, but more like slate in softness, and easily broken into thin layers, and what is exposed to the eye might be pounded to gravel without much labor. A specimen of this, taken about midway between Waynesborough and Staunton, contained 46.100 of calcareous earth; another, taken near Lexington, on the road to the Natural Bridge, contained 80.100. The stone which covers a considerable portion of the Arsenal lot has 84.100, and though much harder than the others, is so soft as to be considered of no value for common purposes, and can be quarried and broken down with a pickaxe. A stone which is very abundant about the Salt Sulphur Springs, is so hard, in the earth, as to yield only to the force of gunpowder, yet crumbles to small gravel after a few weeks' exposure to the air. This contains only 17.100, and is too poor to pay the expense of blasting, but would be worth using, if already exposed to the air. These specimens were selected almost by chance, and even if some judgment had been exercised, it would require many more examinations to prove the strength or worth of any large bodies of such substances; and they are mentioned only to show that such manures may be found, and are worth your seeking. Another calcareous rock is found in limestone streams, which is richer than my best shell-marl, and nearly as soft: I mean that deposite of limestone water, to which the name of *marl* is as incorrectly applied in the upper country, as here to our fossil shells. This is nearly pure calcareous earth, and so far as its quantity will go it must be a very cheap as well as rich manure. In these rocks I should expect to find resources for the improvement of land; but at the same time that I offer them to your notice, I am sensible that the very descriptions given most probably show how little I am acquainted with the substances recommended.

It may be objected that calcareous manures, the particles of which being as coarse as gravel and not very soft, would not be reduced in the soil, and would consequently remain nearly worthless. Certainly the most minute division is best, and therefore 100 bushels of burnt lime, may be expected to exert as much power on the first crop, as 200 bushels in a coarser state; and it may be admitted further, that particles of limestone, or shells, would for many years defy the decomposing powers of air, moisture and frost, which are commonly supposed the only agents for producing this effect. But however hard and insoluble these small fragments may seem, I believe a soil that requires lime, will completely dissolve all of moderate size in a few years. Such at least, is the invariable effect found, when a once acid soil is ploughed up for the second rotation, after applying the fossil shells, unless they were of the largest or hardest kinds, or the dressing unnecessarily heavy. Another fact will prove that this solvent action is peculiar to such soils as I have called acid. On our

river lands, spots may be seen whitened with thin bits of muscle shells, which have been exposed at or near the surface for thousands of years, and to the action of the plough for the last century; yet muscle shells, which on those places appear so indestructible, are thinner, softer, and, from the animal matter they contain, more easy to crumble than the fossil sea shells which are used for manure. The acidity, or something equivalent to acidity, in the one soil, and the absence of it in the other, will serve to account for the very different effects produced.

Yours, &c.

E. RUFFIN.

MANAGEMENT AND BREEDS OF HOGS IN MIDDLESEX, MASSACHUSETTS.

From the Fourth Report of the Agriculture of Massachusetts.

We have been compelled, however, in this, as in many other cases, to witness the capriciousness of public favor; and to adopt, with the variation of only a letter, the familiar proverb, and say in this case, that "every hog must have his day." The popularity of the Berkshire swine is on the wane. It is objected to them by many farmers that they are not large enough, though they are easily made to reach, at fourteen months old, 300 or 350 lbs.; and further, that they do not cut up well; and that the fat on their backs and sides is not thick enough, especially for packing down for fishermen, who would be glad to have their pork all fat, and whom I have seen spread their uncooked salted fat pork, as landsmen spread butter, on their bread.

The former objection is not made by all persons, as many would prefer for their tables the pork of a hog weighing 300 lbs. to that of hogs weighing 600 lbs. of which I have seen many in our market. With respect to the latter objection, I was half disposed at first to consider it as mere caprice, but that E. Phinney, of Lexington, a farmer in this matter "not unknown to fame,"—and another most respectable farmer of Franklin county, admit that there is some truth in it; and they, as well as many others, prefer a cross to the pure blood. The impression is becoming general, and the butchers in Quincy market are unanimous in their unfavorable opinion of the Berkshire hogs. They admit that their hams and shoulders are good for bacon; but their backs, where they most require it, have no depth of fatness, and they are therefore unsuitable for salting. They are good breeders and nurses. They may be kept, therefore, to much advantage where the object is to raise roasting pigs for the market. This is sometimes quite profitable where a sow has two litters a year. A roast pig, only weaned by the knife, has from time immemorial been deemed a most luxurious dish. So it is likely to continue to be. Charles Lamb says that the Chinese never knew the lusciousness of a roasted pig until an accidental fire occurred which destroyed a pig-sty with its inhabitants. In pulling the bodies of these poor creatures burnt to a crisp from the fire, some of the skin or flesh adhered to the fingers of the Chinese, and in putting their hands by chance to their mouths, they for the first time in their lives inhaled the odor and tasted the deliciousness of the roasted skin. After that, the *accidental* burning of pig-sties became so common that the civil authorities were compelled to interpose.

It is but just, however, to the Berkshires to say, that the unfavorable impression in regard to them, though general, is not universal. An intelligent and very exact farmer at Braintree, B. V. French, has found them to answer his expectations. Upon recently killing a number, he was well satisfied with their appearance, and is of opinion that much of the prejudice which exists against them belongs properly to the impure but not to the genuine race.

The introduction of the Chinese hogs into this country and into England seems to have been the foundation of all the extraordinary improvements which have taken place in this race of animals—improvements which, within less than half a century, have doubtless enriched the state of Massachusetts many hundreds of thousands of dollars, and the country by millions. The effects of this cross with other swine have been to give fineness of bone, plumpness and fulness of form, extraordinary thriftiness, and quietness of demeanor. The old race of hogs seemed to be of the wolf species in temper as well as condition, and were the personification of ugliness and rapacity. The first introduction of one of these animals into a secluded part of Scotland, within the last century, is matter of comparatively modern history. Having got loose from his sty, he appeared to the terrified imaginations of these simple people as the arch-fiend himself, and crowds hovered together through fear—the parish schoolmaster being at their head with an open Bible, to endeavor to lay this evil spirit! The animal now, in his improved condition, is regarded as one of the farmer's best friends; he eats what nothing else will eat; he is a general scavenger, and an excellent composter of manure. His own manure is one of the most enriching substances which can be supplied to the soil, though not one of the most lasting in its effects; and his flesh is the most frequent dish upon the farmer's table. This county may boast of great improvements in their swine. A Mr. Mackay, of Boston, owning a farm in Weston, obtained from abroad, some years since, a valuable hog, whose natural good qualities by good management he greatly improved. Some of this breed of swine have been most remarkable for thrift and weight. Besides this, a hog called the Mocho hog, long, round and thrifty, whose pedigree is not known, has been introduced here. Some of the best hogs which I have seen have been from an admixture of these three bloods. Mr. Phinney emphatically approves this cross; and the weight of his swine when killed, of some of which I subjoin an account, establishes the soundness of his judgment.

In 1840, Mr. Phinney sent the following hogs to market:

	Feb. 6.		Feb. 15.		Feb. 17.	
	lbs.		lbs.		lbs.	mos. old
1	weighed 407	1	w'd 469	1	w'd 763	20
2	" 414	2	" 367	2	" 591	15
3	" 413	3	" 362	3	" 476	15
4	" 305	4	" 331	4	" 430	12
5	" 364			5	" 475	12
6	" 366			6	" 465	12
				7	" 430	12
				8	" 464	12

In 1841, the subjoined is a list of fifteen Berkshire and Mackay hogs from the same farm:

February 22, 1841.

		lbs.			lbs.			lbs.
1	weighed	738	1	weighed	528	1	weighed	487
2	"	655	2	"	523	2	"	480
3	"	579	3	"	517	3	"	476
4	"	574	4	"	503	4	"	441
5	"	556	5	"	501	5	"	400

The grass-fed hogs, which I have before mentioned, are regaining their popularity. They have been, to a degree, crossed and intermixed with various valuable breeds in the interior, and are now preferred to all others in the Brighton market. With good care and keeping, at fifteen and eighteen months old they are easily carried to 500 and 600 pounds.

Of four, fatted by Stephen Morse, of Marlborough, the current season, the weight was as follows: 539 lbs., 530, 506, 459—averaging 508½ lbs. each. These hogs were put into the sty in September, 1840, weighing between 70 and 80 lbs. each, and were killed in October, 1841. They were kept mainly upon boiled potatoes the firs winter, and since that, upon the slops of the dairy, skim milk, butter milk, whey and Indian meal.

Some of the best hogs which I have ever seen have been fatted at the slaughtering establishment of Jesse Bird, in Watertown. He keeps his swine about six months. He purchases the grass breed above mentioned, preferring hogs with a small head, round and full body, though not deep belly, and with full shoulders and broad backs. They are taken in, weighing from 170 to 200 lbs., kept in the slaughter-yard for a time, and previous to killing, are fed upon potatoes and Indian meal cooked, and are brought to weigh from 450 to 600 pounds.

At the slaughtering establishments in the vicinity of the capital, large amounts of pork are supported and fatted upon the offal. Sometimes this is cooked for the swine; in other cases it is given in its raw state, so that without any troublesome change in the way of preparation, the hogs eat the cattle and then men eat the hogs. It is easy, but not agreeable to imagine in such cases what the pork may be. The richness of animal food becomes thus a little too much concentrated even for the epicurean palate; and few persons knowingly would have the courage to touch such food when coming directly from the slaughter-yard, excepting some, who are cannibals by nature, and by some accident have been misplaced in a civilized country. It answers very well for shipping pork, for no questions of taste are ever held over a barrel of provision either on a slave plantation or at sea. It is ascertained, however, that in fatting swine, some portion of animal food and pot liquor is highly conducive to thrift. In the best establishments, the hogs, some time before being slaughtered, are put upon vegetable food, potatoes, Indian meal, &c., so that the rankness of the pork is taken away.

E. Phinney's swine establishment, at Lexington is among the most extensive in the county. His number of fattening swine averages about 100, with 50 store hogs, and they are killed in February and March, when from 10 to 18 months old, being of the fall and winter litters of the previous year. His pens are well arranged; seldom occupied by more than three or four in a pen. They have a manure-yard attached to each pen, into which bog-mud and litter are thrown for their manufacture and compounding, and they have always a dry and comfortable bed. They are fed regularly three times a day. I shall subjoin an account given by himself of his mode of management, which the farmers will read with interest.

* * * * *

"An inquiry is often made as to the best time of killing, or at wheat age it is most profitable to slaughter them. On a large farm where much green herbage is produced and where the value of the manure is taken into the account, the pigs killed at the age of 15 and 16 months, give the greatest profit. When it is intended to kill them at this age, they may be kept on more ordinary and cheaper food for the first 10 or 12 months, or till within 4 or 5 months of the time of killing. The manure they make and the extra weight of pork more than pay the expense incurred in keeping them the longer time; but the spring pigs which are to be killed the ensuing winter and spring, must be kept upon the best of food from the time they are taken from the sow until they are slaughtered.

"The older class of pigs for the first 10 or 12 months are kept principally upon brewers' grains, with a small quantity of Indian or barley meal, or rice, ruta-baga, sugar-beet, &c., and in the season of clover, peas, oats, cornstalks, weeds, &c., they are cut green and thrown into the pens; the next 4 or 5 months before killing they have as much Indian meal, barley meal or rice, with an equal quantity of potatoes, apples or pumpkins, as they will eat, the whole being well cooked and salted, and given to them about blood warm. During the season of fattening, an ear or two of hard corn is every day given to each pig. This small quantity they will digest well, and of course there is no waste. Shelled corn, soaked in water made as salt as the water of the ocean for 48 hours, with a quart of wood ashes added to each bushel and given to them occasionally in small quantities, greatly promotes their health and growth. Their health and appetite is also greatly promoted by throwing a handful of charcoal once or twice a week into each of their pens. Their principal food should, however, be cooked thoroughly and nicely. From long practice and repeated experiments, I am convinced that two dollars' worth of material well cooked, will make as much pork as three dollars' worth of the same material given in a raw state.

"Pigs when first taken from the sow should be treated with great care, to prevent them from scouring and becoming stinted; when either of these happen, it will require many days and sometimes weeks to put them again into a healthy growing condition. When first deprived of the maternal food, a little new or skim milk, boiled and slightly salted and given to them often and in small quantities, will prevent scouring and greatly promote their growth. If intended for killing at the age of 9 or 10 months, they should be full fed all the time and kept as fat as possible. If, on the other hand, they are intended for killing at the age of 15 or 18 months, they should not be full-fed, nor be made very fat for the first 10 or 12 months.

"To satisfy myself of the benefit of this course, I took 6 of my best pigs 8 weeks old, all of the same litter, and shut them in two pens three in each. Three of these I fed very high and kept them as fat all the time as they could be made. The other three were fed sparingly, upon coarse

food, but kept in a healthy, growing condition, till within 4 or 5 months of the time of killing, when they were fed as high as the others. They were all slaughtered at the same time, being then 16 months old. At the age of 9 months the full-fed pigs were much the heaviest, but at the time of killing, the pigs fed sparingly, for the first 10 or 12 months, weighed, upon an average, fifty pounds each more than the others. Besides this additional weight of pork, the three "lean kine" added much more than the others to my manure heap. These results would seem very obvious to any one who has noticed the habits of the animal. In consequence of short feeding, they were much more active and industrious in the manufacture of compost, and this activity at the same time caused the muscles to enlarge and the frame to spread, while the very fat pigs became inactive, and like indolent bipeds, they neither worked for their own benefit nor for that of others.

"For the purpose of increasing my manure heap, my pens are kept constantly supplied with peat or swamp mud, about three hundred loads of which are annually thrown into my sties. This, with the manure from my horse stable, which is daily thrown in, and the weeds and coarse herbage which are gathered from the farm, give me about 500 cart loads of manure in a year.

"On regular and systematic feeding and clean and dry bedding, the success of raising and fattening swine very much depends. A faithful feeder, also, who has some skill and taste and withal a little pride of vocation, is indispensable."

Of all articles ever given to fatting swine Indian meal is, without doubt, the most nutritious. Mr. Phinney, it seems, has by actual trial settled a much vexed question, whether hogs should be forced by full feeding when young, or at first be only kept well in a growing state. He found it better, when designed to be kept more than a year, to let the young animal, by sufficient but not excessive feeding, have time to develope himself and acquire a natural size, rather than, by filling him to repletion, to bring on a premature state of fatness, which seemed to check the growth. To young pigs, milk, whey and buttermilk are the best of all feed; but where cows are kept for the purpose of supplying the market with milk, the pigs will be of course regarded as very poor customers. "The milkman will not call." There is however, as I have shown before, under some circumstances, a mistake in this matter.

The establishment of J. P. Cushing, Watertown, for keeping and fatting swine, is upon a large scale, and is exceedingly well contrived for his situation. It consists of a long one-story building, with separate pens on one side extending the whole length, each designed for four swine, with an open yard and a lodging and eating room to each besides some lying-in apartments.* A commodious passage-way runs the whole length of it, with the troughs projecting into the passage-way, and a shutter for the troughs so contrived that the trough is easily cleaned at any time, and the food of the hogs is placed before them without admitting that which, in the usual slovenly mode of feeding, is but too common, an uncivil interference on their part before all is ready. Some contrivance as effectual as this for another class of animals would be quite useful at some of our public hotels and steamboats, and save us from the severe remarks of those foreign travellers who have little sympathy with our customary despatch of business, and seem to look upon us as a nation of fire-eaters.

The cooking apparatus is at one end. Had economy of room and ease of feeding been studied, the building might have been double the width, with pens on each side. In England, they are sometimes made circular with the cooking apparatus in the centre and the feeding troughs all within the circle; but in such cases there must be much waste of room. Mr. Cushing's barracks are lengthwise of his cattle-yard, so that the manure from the pens of his swine is thrown immediately into the yard, and any litter or muck easily supplied in the same way. His store hogs, too, at pleasure may be turned into the cattle-yard with the advice given in Æsop's fable by the dying father to his sons, "that there is a treasure buried in the field which they would find by digging for it." The swine however do not much need the advice. They are natural philosophers and go by instinct into deep investigations. Some of them should always be kept in barn-yards and cellars. They are of great use in turning up and mixing the manure; and in yards where cattle are fed upon grain, and the sweepings of the barn floors are thrown out, they take care that nothing is lost. I have known a considerable number of store hogs kept in a thrifty condition upon that only which they obtained in a yard where a proportional number of beef cattle were stall-fed. The philosophy of reciprocal uses, which is apparent in every department of nature, though it frequently presents itself in a form offensive to a fastidious taste, is to a reflecting mind always instructive on the wonderful economy of the divine providence.

A very large hog establishment in this county is to be found in West Cambridge on the farm of Abner Pierce. He keeps in his enclosure about 500 hogs. They are supported upon the city swill or refuse. No hogs are allowed to be kept in Boston but by special and extraordinary permission; and among the excellent municipal regulations, the refuse vegetables, meat, garbage, and offal of the houses are required to be kept by each householder in a box or barrel which is emptied once a week or oftener by the city scavengers. This, being taken into the covered city carts, is delivered at Mr. Pierce's establishment, about five miles from the city, daily—he paying therefor to the city 4000 dollars per year on a contract for five years.

His hogs, when I visited him, were in an enclosure of about fourteen acres, partly covered with trees and bordering on one of the beautiful ponds in that vicinity, a picturesque situation most certainly, for animals making such humble pretensions to taste and sentiment. If nothing else, however, in the summer months they enjoy, as much as their betters, the luxury of a refreshing bath and quiet repose under the shade, both essentially conducive to their health and thrift.

* The length of this building, including the cooking-place, is 252 feet, width 12 feet, and height the same. There are twenty pens, each 12 feet by 8, and a yard of 12 feet attached to each pen. The number of hogs that can be accommodated depends upon their sizes—from three to six, say an average of four of 300 weight each. There were fatted fifty-two hogs last season, weighing, dressed, 15,573 lbs.

He has had no general disease among them, though occasionally a case of the "blind staggers." He considers this troublesome disease as proceeding wholly from indigestion; and he finds no difficulty in its cure, by procuring an immediate evacuation. For this purpose he gives a dose consisting of half a pint of lamp oil, and half a pint of molasses, strongly charged with pounded brimstone. This remedy is important to be known, as the disease is not uncommon among swine, and often proves fatal. This disease can hardly be considered local, though the "blind staggers" in years gone by, has been known to prevail in some localities near at least one of these ponds among a class of animals, who assume to be of a higher rank, but who occasionally pollute these beautiful regions by a resort to them for purposes of dissipation; but a simple and perfect preventive is at last found for *this* disease, (so much more humiliating and dreadful in its effects on *them*,) if they can be induced to take it, in "total abstinence."

Mr. Pierce's hogs are purchased; he raises none. He buys them at a weight of 100 to 150 lbs. Their average weight when killed, is from 250 to 300 lbs. He has a killing twice a year, though many of his hogs are kept a year. The supply of refuse from the city, is sufficient, excepting at certain seasons of the year, when some meal and corn are given. They fatten in the yard without extra feed, excepting as above. At killing, the skins (that is the small entrails) are sold at 10 cents a set; the harslet at 8 cents; which pay fully the expenses of dressing. The remainder is cooked for the swine, after saving and selling what can be used by the soapmaker. The manure made in their beds where they are littered, is sold readily at four dollars per cord and in quick demand. The average sales of manure are not less than one thousand dollars.

In the enclosure there are extensive plank platforms on which the garbage is spread when brought from the city. The right of cleaning the tables, after the hogs have filled themselves, is purchased by several neighboring farmers at $2 50 per day. Much of the refuse thus obtained is spread upon their grass lands, or ploughed in on their cultivated grounds, or placed round their apple trees, and in every case with the greatest advantage. If not used immediately it is put into a compost heap and covered with mould. Some farmers who obtain it use much of it for feeding their own swine. One farmer stated to me that he had purchased the right of obtaining it two days in a week. He kept the last year fourteen hogs entirely upon these gleanings. The gain upon these hogs in live weight from 1st October to 1st April, when he sold them on foot, was 2800 lbs. Other farmers have been equally successful in this economical process.

The average gain of the hogs at this establishment is rated at a pound per day, live weight. A large amount of bones are brought out in the carts, and these find a ready sale at the bone-mill for manure.

The question of profit in keeping and fattening swine has been much discussed, and so much depends on circumstances of age, breed, food, length of time kept, and price in the market, that the question must remain open. Mr. Phinney gives it as his opinion that with Indian corn at one dollar per bushel and potatoes at 33 cents, and the price of pork 12 cents, they may be fatted to a profit. In his experience, he says, four quarts of Indian or barley meal with an equal quantity of apples, pumpkins, potatoes or roots cooked, will give two pounds of pork.

A small example of fatting swine in Medway, Norfolk county, which came under my notice, seems worth recording, because an exact account of their cost was kept. The owner was a mechanic and bought every article of their feed, not even keeping a cow. His two hogs when killed weighed, one 420 lbs.—one 382 lbs., and pork was then worth 12 cents per lb. Value when dressed $96 24 cts. They were killed at 14 months old. They were bought in November and killed in the December of the next year. They were kept in the sty the whole time; were fed three times a day with weeds, corn and potatoes. The potatoes were boiled and the Indian meal mixed with them into a mash. They were fed exclusively on corn one week before being killed. They did as well in winter as in summer. Salt was frequently given to them in their swill. The price of corn bought for them was 117 cents to 136 cents, or an average of 130 cents per bushel. Potatoes were 30 cts. per bushel. The whole cost of the hogs when fatted was $62 including the price of purchase, or 7.8 cts. per lb.

I shall here subjoin some careful experiments made by myself a few years since in relation to this subject. They were given to some portion of the public at the time, in another form; but they may here reach many by whom they have not been seen, and to whom they may be interesting.

Experiment 1. Two hogs about one year old; one of them a barrow in very good condition; the other a barrow recently gelded and in ordinary condition, were put up to be fed exclusively upon Indian hasty pudding or Indian meal boiled with water. We began feeding them the first of March, 1831, and weighed them again on the nineteenth of the same month. In the eighteen days they consumed six bushels of Indian meal. They were offered cold water to drink but did not incline to take any. The result—

No. 1 weighed on 1st March, -	233 lbs.
" " 19th " - -	269
gain	36
No. 2 (recently gelded) weighed on 1st March	190
" " 16th "	247
gain	57

The gain of the two was 93 lbs. in 18 days. The quantity of meal consumed by them was 10 quarts per day to the two. We allow 30 quarts to a bushel deducting two for grinding. The price of corn at the time was 70 cents per bushel. The expense of the increased weight is 4.5 cents per lb.

March 21, 1831. Killed the hog mentioned first in the foregoing experiment. Live weight 273 lbs. Weight when dressed 215 lbs. Loss in offal, loose fat included, 58 lbs. or a little more than one fifth.

Experiment 2. No. 2 mentioned above weighed

on 23d March, -	253 lbs.
do. on 30th April, -	312
In 38 days, gain,	59 lbs.

No. 3, a shoat purchased from a drove weighed
on 28th March, - 100 lbs.
do. on 30th April, - 151

Gain in 33 days, - - - 51 lbs.

This is a fraction over 1 lb. 8 oz. per day each, nearly 1 lb. 9 oz.

In this case their food was exclusively boiled potatoes mashed with Indian meal. The exact amount consumed not ascertained, but fed as freely as they would bear.

Experiment 3. The two last-named hogs were for the next 20 days put upon Indian hasty pudding exclusively, with the following result:

No. 2 weighed on 30th April, - 312 lbs.
" " 20th May, - 382

Gain in 20 days, - - 70 lbs.
No. 3 weighed on 30th April, - 151
" " 20th May, - 185

Gain in 20 days, - - 34 lbs.

The two in the above named 20 days, consumed 4½ bushels of meal, cooked as above. Meal 78 cents per bushel. Gain of the two, 104 lbs. in 20 days.

Experiment 4. Sundry swine purchased from a drove, and fed with meal and potatoes, washed and mashed—

	28th March, 1831. lbs.	19th May, 1831. lbs.		lbs.
No. 1 weighed	97,	165,	gain in 52 days	68
2 "	134,	182,	" "	48
3 "	100,	186,	" "	86

The two following, raised on the farm, and fed as above—

	25th April, 1831. lbs.	19th May, 1831. lbs.		lbs.
No. 4 weighed	151	206,	gain in 24 days,	55
5 "	140	165,	" " "	25

Experiment 5. In this case it was not intended to force their thrift, but to keep the swine in an improving condition. They were shoats of the last autumn, and were of a good breed.

Tuesday, 3d April, 1833. Put up four shoats, and began feeding them with Indian hasty pudding.

	3d April.	22d April.		25th June.	
No. 1	176 lbs.	202 lbs.	gain 25	264 lbs.	gain 62
2	119	153	" 34	226	" 73
3	150	170	" 20	218	" 48
				[Total 183 lbs.	
4	121	145	" 24	Killed May 30.	

From 3d April, to 22d April, the above swine consumed seven bushels and one peck of Indian meal. From 22d April, to 25th June, seven bushels of Indian meal, cooked as above.

One of the above, No. 4, was killed on 30th May; being absent, the live weight was not ascertained.

On the 25th June, the three remaining hogs were weighed, and in the 63 days from 22d April to 25th June, they had gained in that time 183 lbs. as above.

After 30th May, when one of them was killed, one peck of meal made into hasty pudding with a small allowance of the waste of the kitchen for a part of that time, lasted them three days, that is 22-25 or less than a quart, say ⅞ of a quart per day to each.

At first we employed half a bushel of Indian meal to make a kettle of hasty pudding; but we soon found that a peck of meal by being boiled sufficiently would make the same kettle nearly full of hasty pudding and of sufficient consistency. The kettle was a common-sized five-pail kettle, set in brick work in the house; and it was remarkable that the peck of meal produced nearly the same quantity of pudding, that we obtained from the half bushel, which showed the importance of inducing the meal to take up all the water it could be made to absorb.

The price of Indian corn was at that time 75 cents per bushel—30 quarts of meal to a bushel deducting the toll. The amount of meal consumed in the whole time from 3d April to 25th June was 14¼ bushels—the cost $10 69—the total gain, making no allowance for the gain of No. 4, from 22d April to 30th May, which was not ascertained, was 287 lbs.

The gain of No. 1, 2 and 3, from 22d April to 25th June was 183 lbs. in 63 days; and allowing one peck to serve the three hogs for three days, required 5¼ bushels, the cost of which was $3 94. The live weight could not be estimated at less than 4 cents per lb. when pork was at market 6 cents.

The value of the 183 lbs. therefore was equal to $7 32, or at 5 cents to $9 15 cents.

The gain of the swine for the first 19 days, from 3d to 22d April, was:

No. 1, 26 lbs. or 1.368 per day.
" 2, 34 " or 1.789 "
" 3, 20 " or 1.052 "
" 4, 24 " or 1.263 "

The gain from 22d April to 25th June, 63 days, was:

No. 1, 62 lbs. or 0.984 per day.
" 2, 73 " or 1.158 "
" 3, 48 " or 0.761 "

The difference of daily gain in the two periods was attributable to the diminished quantity of meal. The question then arises, whether the first mode of feeding was as economical as the second.

In the first 19 days, 7 lbs. 1 peck consumed, gave 104 lbs. gain. In the next 63 days, 5 lbs. 1 peck consumed, gave 183 lbs. gain.

Had the first gain been in proportion to the second gain in reference to the meal consumed, the 7¼ bushels which gave 104 lbs. should have given 252 5-7 lbs. This great disparity can be explained only in the more economical preparation of the meal, by which a peck, taking up as much water as it would contain, gave a kettle nearly full of pudding, when half a bushel of meal imperfectly prepared, gave little more. This seems to demonstrate the great advantage of cooked food, both as it respects its increase of bulk and the improvement of its nutritive properties. Whether it would apply to those substances, whose bulk is not increased by cooking equally as to Indian meal and the like, is a matter which experiments only can determine.

Such are some few trials in reference to the feeding and fattening of swine, which I have made, or information of which I have obtained from other sources, which may at least lead the inquisitive farmer to further experiments and inquiries, on a subject of great importance to his interest. The inferences to be made from them I shall leave to others. The results, as will be observed, are not uniform. The thrift of animals must depend on various other circumstances

besides the kinds or the quantity of food given them. Much depends on the breed, as every farmer knows; much on the health of the animal; something on the season of the year. I failed in attempting to fatten several swine in one case, though they were carefully attended and various kinds of feed were tried, and the failure was totally inexplicable until they were slaughtered, when the intestines were found corroded with worms, resembling those found in the human stomach, and this, I have no doubt prevented their thrift. The same fact has occurred in another instance, and with the same result. I failed in attempting to fatten some other swine, who had been driven a considerable distance and exposed, probably not even half fed on the road, to severe cold and storms. Some of them were frost-bitten in their limbs; and though attended and fed in the most careful manner they made no progress for months. In an experiment recently made, of giving swine raw meal mixed with water, I have found a falling off in their gain of nearly one half, compared with giving their food cooked, such as boiled potatoes and carrots, mixed with meal while hot; the result being in a sty containing a number of swine, as 279 to 500. In respect to confinement or freedom, various opinions are entertained. The Shakers at Canterbury, N. H., deem it indispensable to the thriving of their swine that they should have access to water to wallow or to wash themselves in; and that they by no means do so well without it. On this point I have had no trial further than to satisfy myself that fatting hogs are sometimes injured by being suffered to root in the earth.

With respect to the age at which it is advantageous to put up swine to fatten, I have only to remark, that it is with swine as with other animals, there are some breeds which come much sooner to maturity than others. A successful farmer in Saratoga county, N. Y., says that March pigs, killed about Christmas, are the most profitable for pork. Four pigs of what is called the grass breed, were slaughtered at Greenfield, N. Y., which weighed 348 lbs., 318 lbs., 310 lbs. and 306 lbs. at nine months and seventeen days old.

On this point, I present a letter with which I was honored by the late John Lowell, whose authority in the agricultural community is justly estimated.

"*Dear sir:*—I have been prevented answering your inquiries as to my experience in raising old or young pigs. I may say that I have fully and clearly ascertained, from a trial of 20 years, that young pigs of from 25 to 30 lbs. will give nearly double, in some remarkable case three times as many lbs. as shoats of 6 months weighing from 100 to 150. I have taken two pigs of 100 lbs. each, age six months, and never was able between May and November, to get them above 180, rarely above 170. I have taken three pigs of about 30 lbs. each, and on the same food which I gave to the two, they would weigh from 170 to 180 each in the same period;—nay I have taken pigs of 200, and never could get them to weigh more than 300 in 7 months on my food. The way I ascertain the quantity of food is, that I never give any thing but the produce of my dairy, and the refuse of the garden, peaches, apples, and cabbage, which are uniform generally.

"3 pigs of 90 wt. or 30 wt. each, will give ordinarily 510 lbs.
less original wt. 90 often not more than 60.
gain 420 lbs.

2 pigs of 100 wt. each, will give ordinarily 340 lbs.
less original wt. 200
gain 140

"But the 3 pigs of 90 will not consume for the first 3 months half so much as the 2 of 100 each, and I have kept a 4th and sold it in August for quarter pork.

"There is nothing new or remarkable in these facts. It is the law of the whole animal creation. It is true of the calf and of man. The child of 7 lbs. quadruples its weight in 12 months; and the calf of 60 wt. if fine and well fed will weigh 600 wt. at the end of the year, and (if a female) will not double the last weight at any age.

"P. S. It should be remarked that the weight at purchase is live weight, and at sale dead or net weight, because in truth, to the owner this is the true mode of considering the subject. No doubt my sort of food is peculiarly favorable to young animals, it consisting in very liberal allowance of milk. If the older pigs were at once put on Indian meal they would attain to 250 lbs. at a year old, but the cost of the meal at 70 cts. per bushel would amount to 9 dollars, and if the first cost, 5 dollars 50 cents, be added, and the pig sold at 6 cents, there would be but 2 dollars gain on 2 pigs of 100 lbs. each; while 3 small pigs without meal fed on milk would give 24 dollars in the same time. I do not mean to give minute details but general views. As an important qualification of the foregoing statement it should be added, that shoats of 6 months bought out of droves have usually been stinted in their growth, and animals like trees, recover slowly after a check. I presume if shoats were taken from a careful and liberal owner the difference would be less. But as a general law it may be safely affirmed, that weight for weight at the purchase, the younger the animal the greater the positive, and the far greater the net gain. At least such is my own experience and belief."

The preceding facts and experiments encourage the belief that hogs may be raised and fattened by the farmer to advantage, where corn is worth about 70 cents per bushel, and his pork will bring him 6 cents per lb. Success must greatly depend on skill, care, selection, and good management. The best swine that I have ever found have been in dairy countries, for there cannot be a doubt that milk and whey for every animal are among the most nutritious of aliments. Indian meal probably ranks next, though many farmers prefer a mixture of provender, such as corn, oats, rye, or barley; but I believe in all cases cooked food will have a decided advantage over that which is given in a raw state: an advantage more than equivalent to the labor and expense of its preparation. Potatoes are a valuable article of food, but the pork is not so good as that fattened upon corn. Carrots are more nutritious than potatoes. Corn given in a raw state or on the ear is a most wasteful management.

Swine ought to be kept on every farm in sufficient numbers to consume all the offal and waste of

the dairy and kitchen. If, beyond this, a breed can be obtained, which will arrive at early maturity, and which can be advantageously grass-fed or kept at a small expense and in an improving condition through the summer; and being put up to fatten early in autumn and forced as much as possible so as to be sent to market early in the winter, the farmer will ordinarily find a fair profit in this branch of husbandry. A great advantage is found in the keeping of swine from the valuable returns of manure, both in quantity and quality, which are obtained from them, where care is taken to supply them with raw materials for the manufacture. Too much care cannot be bestowed in the selection of the breed and the general health of the animal when put up to feed; and it is strongly recommended to every careful farmer occasionally to weigh the animal and measure the feed, that he may ascertain seasonably on which side the balance of debt or credit is likely to fall. Nothing is more prejudicial to good husbandry than mere guesses and random conjectures; and though the result of our operations may not meet either our wishes or expectations, an intelligent mind will be always anxious as far as practicable to know precisely how far they correspond with or disappoint them.

The profit of fatting pork with us has become much more questionable since such vast amounts of salted pork and hams are brought into our markets from Ohio and the far western states, through the great and constantly increasing facilities of transportation. It is judged that much more than a year's supply is now on hand in the city of New York, and the new has not begun to come in.

This must essentially affect our markets. But it is to be considered that to a certain extent our own pork here will always be preferred; and that fresh pork, the lean pieces, will always be wanted in our market, with which the western pork can not at present come into competition, though after the experience of the last five years, it might be almost rashness to say that our markets may not yet be supplied with roasting pigs and fresh spareribs from Cincinnati. Then again there is on every farm a certain amount of refuse and offal, which may be profitably given to hogs, and would otherwise be lost. There is another circumstance, which must go to the credit of our swine. Manure in Middlesex county is every where valued at least at 4 dollars per cord on the farm. A hog duly supplied with the raw material, for a hog cannot, more than an Israelite, make bricks without straw, will make three cords of valuable manure in a year. A sow well kept likewise may raise a litter of pigs, and may be fitted for the market in the same year. These circumstances may encourage us to think that, in spite of western competition, a certain amount of pork may be profitably fatted among us every year. It is comparatively a recent discovery that apples are as good for fatting swine as potatoes. This opinion has been expressed to me by many farmers in this county. Apples may be cultivated to an indefinite extent and at a small expense. We may easily avail ourselves of this advantage. The opinion of many of these farmers is, that they are better given raw than cooked. This point will, I hope, be made matter of experiment. The fatting of hogs, however, is subject to so many contingences, that under present circumstances, excepting where extraordinary supplies of food are easily obtained, upon a large scale, it can be safely undertaken only with extreme caution and care. Many, who have undertaken it, have been unsuccessful.

THE FARMERS' REGISTER.

VOL. X. FEBRUARY 28, 1842. No. 2.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

ON THE PRESERVATION OF MANURE.

From the London Farmers' Magazine.

Sir,—You will be aware that the objects of manure are to restore to the soil those substances necessary to the growth of plants, which are removed in the *crops*. Though this perhaps is not the only point to be considered when treating on *manures*, it is evidently one of the utmost importance. The mechanical influence of the soils is no doubt great, but its consideration peculiarly belongs to the cultivator. In the present letter, I shall endeavor to draw your attention to those manures which are calculated to increase the nutritious properties of the cereal grains, and those grasses which are the indirect means of giving food to man.

The substances removed by crops from the soil must be restored; some plants remove one class of salts, some another; but all those which are fitted to the support of animal life take from the soil the *nitrogen* contained in it. For all plants cultivated for the use of man contain *nitrogen*, and in proportion to the quantity of this element so are the nutritious qualities of the food. The nutritious parts of wheat and all grain are in fact exactly of the same composition as flesh and blood. The following is a statement of the numbers:

	In gluten, the nutritious part of wheat.	*In blood.*
Carbon, - - -	54.603	54.56
Hydrogen, - - -	7.302	6.90
Nitrogen, - - -	15.59	15,72
Oxygen, sulphur, phosphorus,	22.286	22.82*

This shows that nitrogen is a very important constituent in the food of man.

To ill preservation in manure I shall now take the liberty of calling your attention.

Nitrogen is supplied to plants in a wild state from the atmosphere†—in a cultivated state from the soil and atmosphere. In manuring lands then we return to them the nitrogen which has been taken from them in the crops, and we always return it to them in the form of some compound of ammonia. The goodness of manure, or its fitness to restore the nitrogen to the soil, consists in the quantity of ammonia, which is composed of nitrogen and hydrogen, including those substances containing nitrogen which sooner or later will be converted into ammonia or hartshorn by the putrefactive process.

Let us now consider the state of a heap of manure, consisting of animal excrements, liquid and solid, which contain large quantities of nitrogen in the form of ammonia; let us consider, I say, this heap of manure lying exposed to the influence of the weather during a hot summer. The nitrogenized parts are gradually converted into ammonia, and the greater part of this ammonia is volatilized and carried into the atmosphere. We cannot have failed to remark the smell of this body when passing by a heap of manure in a hot day, even though we be at a considerable distance from the spot where the manure is deposited; to taint so large a quantity of air with its smell, would require a large quantity of ammonia; and what passes into the atmosphere is comparatively lost to the agriculturist, or it does him no more good than his neighbors, for it is carried down by the rain and spread equally over the country.

Ammonia or hartshorn possesses the properties in common with all alkalies of uniting with acids, and forming with them in most cases compounds of sparing volatility. All aluminous minerals and those containing *peroxide* of iron possess also the power of condensing the volatile alkali in such a manner that it is not carried away and lost by every gust of wind that passes over the dunghill. Alumina and peroxide of iron are in fact very nearly allied, and possess the property of combining with ammonia in common, one being isomeric with the other. Ammonia, *the active part* of manures, may be rendered fixed, it has been said, by *acids*, and you will allow me to point out the practicability of this plan in the first instance. In *urine* that has undergone putrefaction, ammonia exists as carbonate, phosphate, lactate, &c.; the first of these salts is continually evaporating, and ammonia is set free from all the other salts by adding lime, which is a practice too common. Let us now suppose a manure consisting of these salts mixed with organic matter, to be watered with a weak solution of sulphuric acid (oil of vitriol); the salts of ammonia are decomposed and a sulphate formed—this sulphate is quite fixed. The composition of this sulphate of ammonia is *per cent.* ammonia 39.48, sulphuric acid 60.52. For every 60 pounds of sulphuric acid employed (and it costs but a penny a pound), 39.48 pounds of ammonia are fixed in the manure, and may be kept for any period of time without loss.

We shall see the advantage of this method of proceeding by following the annexed calculation:—100 pounds of hay contain one pound of nitrogen, and every hundred parts of ammonia contain 82.54 *per cent.* of the same element. For every hundred pounds, then, of ammonia, conveyed to the soil in this manner, there will be produced, supposing all the nitrogen to be assimilated in the proportion to form hay, 82,000 pounds of hay.

Calculating the advantages at a much less rate than the above, the profit in nitrogenized parts that will be produced will amply repay the agriculturist for the trifling outlay in sulphuric acid. Indeed, no opportunity of preserving the ammonia produced by animals should be neglected; a few pounds of sulphuric acid being mixed in a diluted state with the manure would be of immense advantage. Throwing down sulphuric acid in all places where excrementitious matter collects, would be a never failing source of nitrogen, containing manure laid up in a safe form ready for use. The absurd practice of using lime for removing those smells caused by ammonia cannot be too much deprecated, as lime immediately set

* Annalen der Chemie und Pharmacie, xxxix. 149.
† Liebig, Agr. Chem.

free all the ammonia which the manure contains, and it is lost.

The manure preserved by sulphuric acid should be thrown in the soil with gypsum, and would be a never failing source of nitrogen. The same good results will arise, though in a less degree, from the use of burnt clay and other aluminous minerals; but from their property of forming insoluble compounds with ammonia, and uniting with no other bases, they are more adapted to the immediate application to the soil, than for being mixed with manure. Another advantage which sulphuric acid possesses is, that it converts all the lime that may happen to be in the soil into gypsum, which is a sulphate of lime.

T. G. T. Ph. D.

ON THE COMPARATIVE FEEDING PROPERTIES OF MANGEL-WURZEL AND SWEDISH TURNIPS.

By the Right Hon. Earl Spencer.

From the Journal of the Royal Agricultural Society of England.

My dear sir,—You expressed a wish that I should again publish the results of an experiment which I made fifteen or sixteen years ago on the comparative feeding properties of Swedish turnips and mangel-wurzel. It was published in the 'Farmer's Journal' of that day, but I believe it is now very little if at all remembered; and I agree with you in thinking that it may be more interesting now, when men's minds are more turned to this sort of investigations.

The mode of ascertaining the nutritious properties of different kinds of vegetable food by chemical analysis, which was adopted by Sinclair and other scientific men, gives a reasonable probability of their relative value; but we know so little of the processes of nature in converting food into the flesh of the animal that consumes it, that this mode has never appeared to me quite satisfactory. Although, therefore, I believed that mangel-wurzel contained more saccharine matter than Swedish turnips, and ought consequently to be the more nourishing root of the two, I determined to try practically whether an ox fed upon mangel-wurzel increased in weight more than one fed upon Swedish turnips, in proportion to the quantity of each consumed. In order to have rendered my experiment perfectly accurate, I ought to have ascertained the weight of hay consumed by each beast during the progress of the trial, but I did not do this, although I am pretty confident that the quantity consumed by each was nearly the same. I selected two steers, tolerably and at least equally well-bred: No. 1, calved March 29, 1823, and No. 2, calved May 6 of the same year; and on the 24th of December, 1825, I put No. 1 to Swedish turnips, and No. 2 to mangel-wurzel. I ascertained their weight by measurement, and both of them measured the same, viz. 4 ft. 10 in. in length by 6 ft. 5 in. in girth, making them to weigh 668 lbs. each. On the 23d of January, No. 1 had consumed 1624 lbs. of Swedish turnips, and measured 4 ft. 10 in. in length by 6 ft. 7 in. in girth, making him to weigh 703 lbs., and to have increased in weight 35 lbs., or at the rate of 48¼ lbs. for every ton of Swedish turnips consumed. No. 2 had consumed 1848 lbs. of mangel-wurzel, and measured 4 ft. 10 in. in length by 6 ft. 8 in. in girth, making him to weigh 721 lbs., and to have increased in weight 53 lbs., or at the rate of 65½ lbs. for every ton of mangel-wurzel consumed.

This difference, however, might have arisen from No. 2 having a greater propensity to feed than No. 1; I therefore now put No. 1 to mangel-wurzel, and No. 2 to Swedish turnips. On the 20th of February, No. 1 had consumed 1884 lbs. of mangel-wurzel, and measured 4 ft. 11 in. in length by 6 ft. 8 in. in girth, making him to weigh 734 lbs., and to have increased in weight this month 31 lbs., or at the rate of 36¾ lbs. for every ton of mangel-wurzel consumed. No. 2 had consumed 1880 lbs. of Swedish turnips, and measured 4 ft. 11 in. in length by 6 ft. 8 in. in girth, making him to weigh also 734 lbs., and to have increased in weight during this month 13 lbs., or at the rate of 15½ lbs. for every ton of Swedish turnips consumed. I then put both to mangel-wurzel, and divided the food equally between them. On the 19th of March, they had each consumed 1792 lbs. of mangel-wurzel; No. 1 measured 5 ft. in length by 6 ft. 10 in. in girth, making him to weigh 784 lbs., and to have increased in weight 50 lbs.; No. 2 measured 5 ft. in length by 6 ft. 9 in. in girth, making him to weigh 765 lbs., and to have increased in weight 31 lbs.

It would appear, therefore, as if the propensity to feed of No. 1 was greater than that of No. 2 in the proportion of 50 to 31; but notwithstanding this, in the first month, when No. 1 was upon Swedish turnips, and No. 2 upon mangel-wurzel, No. 2 beat No. 1 in the proportion above stated of 65½ to 48¼. It appears as if there could be no great inaccuracy in estimating the relative weight of the animals, as soon after the experiment was concluded I sold No. 1 to a butcher in the country for 24*l.* 3s., and No. 2 at Smithfield for 24*l.*

It will be for practical men to decide upon the value of this trial; what appears to me to be the most conclusive part of it is, that No. 2, who had during the first month, when he was feeding upon mangel-wurzel, increased in girth 3 in., in the next month, when his food was changed to Swedish turnips, did not increase in girth at all, and when in the third month he was feeding again upon mangel-wurzel he again began to increase in girth, because it is very well known that, if an animal is changed from more to less nutritious food, the probable consequence will be that his growth will be stopped. The results appeared to me so decisive, that I have not tried the experiment with the same accuracy since; but I did try the following year the feeding a cow alternately on Swedish turnips and mangel-wurzel, and though I have not by me the details of the trial, I remember that the result confirmed the experiment of the previous year. Believe me, my dear sir, yours most truly, SPENCER.

Philip Pusey, Esq. M. P.

WORM IN THE KIDNEY OF SWINE.

From the Democratic (Me.) Clarion.

Mr. Editor:—I am induced to send you the following statement, not so much from the importance

of this particular case, as from its being a link in the great chain of testimony in favor of a more humane and improved treatment of diseased swine.

In Oct. last, I observed that a thrifty young shoat of mine was weak in the back: he grew worse for several days, until he could scarcely move about, or even get up. At this stage of disease, I commenced feeding him with corn, boiled soft in strong lie, with the addition of a handful of charcoal. This feed was continued four or five days, at which time the hog had to all appearances become as well as ever, and so continues to this time. J. D. Hill.

No. 3d Range, near Bingham.

OF THE PRESERVATION OF RACES BY SEED.

From Lindley's Horticulture.

The manner of preserving the domesticated races of plants by the ordinary means of propagation, such as cuttings, layers, grafts, and so on, has already been explained; there are, however, some other topics connected with this important subject which require to be touched upon.

Propagation by division is inapplicable to annuals or biennials, or at least can be practised upon only a very limited scale, and for such plants the gardener has to trust to seeds alone. But it is an axiom in vegetable physiology that seeds reproduce the species only, while buds (that is, propagation by division) will multiply the variety; and this is undoubtedly true as a general rule. But the skill and care of the gardener often enable him to perpetuate by seed the many races of cultivated annuals, varieties of the same species, improved and altered by centuries of domestication, with as much certainty as if he were operating with cuttings. In a well managed farm we see the various breeds of turnips and corn preserving each its own peculiar character unchanged year after year, and yet they must all be propagated by seed alone; and in gardens the varieties are innumerable of peas, lettuces, cabbages, radishes, &c., whose purity is maintained by the same means. The manner in which this is effected is of the first importance to be understood.

Although it is the general nature of a seed to perpetuate the species only to which it belongs, and it cannot therefore be relied upon, in ordinary cases, to renew a particular variety of the species, yet there is always a visible tendency in it to produce a seedling more like its parent than any other form of the species. Suppose, for example, the seed of a Ribston pippin apple were sown; if untainted by intermixture with other varieties, it would produce an apple tree whose fruit would be large, sweet, and agreeable to eat, and not small, sour, and uneatable, like the wilding apple or crab. The object of the gardener is to fix this tendency, and he does it by means not unlike those employed in the preservation of the races of domesticated animals, namely, by "breeding in and in," as the phrase is. An example of this will be more instructive than a dissertation. The radish has, when wild, a long pallid root; among many seedlings one was remarked with roots shorter and rounder, and more succulent than the remainder; this was a "sport" to which all plants are subject. Had that radish been left among its companions, and the seed saved from them all indifferently, the tendency would have disappeared for that time; but its companions were all eradicated, and the better one produced its seed in solitude. The crop of young plants obtained from this radish was, for the most part, composed of individuals of the wild form, but several preserved the same qualities as the parent, and some, perhaps one only, in a higher degree: in this one, then, the tendency was beginning to fix. Again were all eradicated, except the last-mentioned individual, whose seeds were carefully preserved for the succeeding crop; and, by a constant repetition of this practice for many years, at last the habit to produce a round and succulent root became so fixed, that all the radishes assumed the same appearance and quality, and there were none left to draft or "rogue." Every variety of annual crop, not still in its wild state, must have gone through this process of fixing; and thus the varieties of earliness, lateness, and productiveness, color, form, and flavor, observable in garden plants, have been secured for our enjoyment.

But to fix a new habit in annual plants is not the only care of the cultivator, whose patience and skill would be ill employed if it could not be preserved. If a plant has some tendency to vary from its original condition, it has much more to revert to its wild state; and there can be no doubt that, if the arts of cultivation were abandoned for only a very few years, all the annual varieties of our gardens would disappear, and be replaced by a few original wild forms.

For the means of preserving the races of plants pure, the means vary according to the nature of the variety. As far as concerns early and late varieties, it often happens that, as in peas, the tendency in such plants to advance or retard their season of ripening was originally connected with the soil or climate in which they grew. A plant which for years is cultivated in a warm dry soil, where it ripens in forty days, will acquire habits of great excitability; and, when sown in another soil, will, for a season or so, retain its habit of rapid maturity: and the reverse will happen to an annual from a cold wet soil. But, as the latter will gradually become excitable and precocious, if sown for a succession of seasons in a dry warm soil, so will the former lose those habits and become late and less excitable. Hence, the best seedsmen always take care that their early varieties of annuals are procured from warmer and drier lands than those on which they are to be sown; our earliest peas, for example, are obtained from France, and the next in time of ripening from the hot dry fields of Kent, the Suffolk coast, and similar situations. Thus, also, the barley grown on sandy soils, in the warmest parts of England, is always found by the Scotch farmer, when introduced into his country, to ripen on his cold hills earlier than his crops of the same kind do, when he uses the seeds of plants which have passed through several successive generations in his colder climate; and Mr. Knight found that the crops of wheat on some very high and cold ground, which he cultivated, ripened much earlier when he obtained his seed-corn from a very warm district and gravelly soil, which lies a few miles distant, than when he employed the seed of his vi-

cinity. It would seem as if this were in some way connected with the mere size of a seed, the smallest seeds of a given variety producing plants capable of fructifying quicker than those of a much larger size. We have, at present, but little information upon this subject; but there are some most curious experiments relative to it by Messrs. Edwards and Colin, who found that, although winter wheat cannot, in France, be made to shoot into ear, if sown in the spring, provided the largest grains of the variety are employed, yet that, if the smallest grains are picked out, some will ear like spring wheat (see *Annales des Sciences Naturales*, v. 1.) Out of 530 grains of winter wheat, sown on the 23d of April, and weighing 7 ounces 52 grains, not one pushed into ear, they tillered abundantly, but the tillers were excessively stunted, and concealed among the tufts of leaves; in short, they formed nothing but turf: on the other hand, of 530 other grains, weighing 3 ounces 56 grains, and sown on the same day, 60 pushed in ear.

It would seem as if many of our most esteemed garden plants were the result of debility, and that the succulence, the sweetness, or the excessive size, which render them so well suited for food, were only marks of unhealthiness. At least, it is almost necessary to assume this to be the case, in order to account for the efficacy of one of the modes of maintaining races genuine. It is perfectly well known, that, if such an annual as a turnip is transplanted shortly before it runs to seed, the characters of its variety will remain more strongly marked, and have far less tendency to vary, than if, all other circumstances remaining the same, the seed is saved without the process of transplantation having been observed. Now, the only effect of transplanting, at the season immediately preceding the formation of a flower-stalk, would seem to be that of checking the luxuriance of the individual operated on; or, upon the above assumption, of increasing its debility of constitution. And the same explanation appears applicable to a strange custom mentioned by Mr. Ingledew as being practised in the Dekkan, to prevent the rapid deterioration, in that climate, of the carrot, the radish, and the parsnip, the favorite table vegetables of the inhabitants. He states that the Indian gardeners, in the first place, prepare a compost of buffaloes' dung, swine's dung, and red maiden earth, mixed with water till they have the consistence of paste, and scented with a small quantity of assafœtida, the latter of which seems to be perfectly useless.

"The vegetables for this operation are drawn, when wanted, from the beds, when they have attained about one third of their natural growth, and those plants are chosen which are the most succulent and luxuriant; the tops are removed, leaving a few inches from their origin in the crown upwards; and a little of the inferior extremity, or taproot, is cut straight off likewise, allowing nearly the whole of the edible part to remain, from the bottom of which to within about an inch of the crown, are made two incisions across each other entirely through the body of the vegetable, dividing it into quarters nearly to the upper end. They are then dipped into the compost until they are well covered by it, both externally and internally, and are immediately placed in beds, previously prepared for their reception, at the distance of fifteen or sixteen inches from each other, and so deep in the ground that the upper extremities only appear in sight. They are afterwards regularly watered; and when they take root, and fresh tops have made some advance in growth, they require but little attention. The tops speedily become large, and grow into strong and luxuriant stalks, the blossoms acquire a size larger than ordinary, and the seed they produce is likewise large and vigorous, and superabundant in quantity. Innumerable roots are thrown out from the incised edges of these plants; they consequently receive a greater abundance of nourishment, which occasions their luxuriant growth, causes them to yield not only a more than ordinary crop of seed, but also of a superior quality." (*Hort. Trans.*, v. 517.) The operation is performed at the beginning of the dry season.

Besides "roguing out" (i. e. eradicating) all individuals having the slightest appearance of degeneracy from among the plants intended for seed, care must be taken that the crop is so far from any other of a similar kind as to incur no risk of being spoiled by the intermixture of its pollen. This substance is conveyed to considerable distances by wind and insects; and it is scarcely possible to be secure from its influence, if similar crops are cultivated within some miles of each other; whence we find certain villages, in different parts of Europe, celebrated for the purity of the seed of particular varieties; this usually happens in consequence of the villagers cultivating that variety and no other, as happens at Castelnaudary with beet, at Altringham with the carrot, and in Norfolk with different kinds of turnip.

It is, however, to be observed, that the deterioration of seed by bastardizing happens to a greater extent to single plants than to large masses of them; and it seldom happens that good seed can be saved in a garden, or near gardens, from a single individual. Solitary specimens of the turnip, the cauliflower, and such plants, have been frequently selected on account of their perfect characters, and been carefully planted in gardens for a stock of seed, but their produce has as frequently been of the worst description, bearing no resemblance to the parent. In such cases as these, it would seem as if bees and other insects were attracted from all quarters by the gay colors, or odor, of such isolated individuals, and, arriving from a hundred flowers which they had previously visited, bring with them so many sources of contamination.

When, however, the action of other flowers can be prevented, as in the melon and other unisexual plants, by "setting," the largest, healthiest, and most cultivated varieties will yield seed of the purest and finest quality. The tendency of Persian melons to degenerate in this country was remarked soon after their introduction; and, for a long time, it was thought impossible to preserve them for many generations. Mr. Knight, in his numberless experiments upon this fruit, found that to be the case; for his fruit, at one time, became less in bulk and weight, and deteriorated in taste and flavor. But when he came to consider that "every large and excellent variety of melon must necessarily have been the production of high culture and abundant food, and that a continuance of the same measures which raised it to its highly improved state must be necessary to prevent its

receding, in successive generations, from that excellence," the cause of his Persian melons deteriorating became apparent; and he found that by bringing the cultivation of the plants to a state of great perfection, he succeeded completely in rendering the original quality hereditary, as long as those precautions were observed. No man was more successful in the cultivation of the melon than Mr. Knight; and it is in the memory of many persons, that the quality of his sweet melons of Ispahan has very rarely been equalled. The peculiar methods that he adopted appear to have been the complete and most careful preservation of the leaves from injury of whatever kind, the full exposure of their surface to light, and the augmentation of the ordinary warmth of a melon bed by availing himself of the heat reflected from brick tiles with which his bed was paved. To such an extent was his care of the leaves carried, that he would not allow even the watering to be performed "over-head," but he caused his gardener to pour water, from a vessel of proper construction, upon the brick tiles between the leaves, without touching them. (See various papers upon the melon in the *Horticultural Transactions*, and especially that in vol. vii. p. 584.)

While, however, such are the general principles upon which the preservation of the peculiar qualities of the many races of cultivated annuals necessarily depends, it must be confessed that, according to report, there are circumstances upon which science can throw no light, and which, if true, must depend upon conditions as yet unsuspected to exist. Of this class is the following, respecting the Brussels sprouts cabbage, given upon the authority of M. Van Mons.

"Much has been said of the disposition of this plant to degenerate. In the soil of Brussels it remains true, and I have lately observed it to do the same at Louvain; but at Malines, which is the same distance from Brussels as Louvain, and where the greatest attention is paid to the growth of vegetables, it deviates from its proper character, after the first sowing: yet it does not seem that any particular soil or aspect is essential to the plant, for it grows equally well and true at Brussels, in the gardens of the town, where the soil is sandy and mixed with a black moist loam, as in the fields, where a compact white clay predominates. The progress of deterioration at Malines was most rapid; the plants raised from seed of the true sort, which I had sent there, produced the sprouts in little bunches or rosettes, in their true form; seeds of those being saved, they gave plants in which the sprouts did not form into little cabbages, but were expanded; nor did they shoot again at the axils of the stem. The plants raised from the seed of these last mentioned only produced lateral shoots with weak pendent leaves, and tops similar to the shoots, so that in three generations the entire character of the original was lost. From a plant in the state last described, seed was saved at my request, and sent back to me. I had it sown by itself, and carefully watched the plants in their growth; I was not long in discovering that they retained the same character of degeneration they had assumed at Malines, and preserved it throughout the whole course of their growth, yielding pendulous leaves with long petioles, and having no disposition to cabbage. I suffered these plants to run to seed at a great distance from my true sprouts, which the extent of my garden allowed me easily to do. The second sowing brought them back a good deal to their true character; the plants yielded small cabbages regularly at each axil, but not generally full or compact, and they did not shoot a second time, as the true sort does. I again suffered these to run to seed, using the same precaution of keeping them by themselves. I sowed the seed, and this time the plants were found to have entirely recovered their original habits, their head, and rich produce." (*Hort. Trans.*, iii. 197.) I must confess, however, that, although the passage merits quotation, for the sake of exciting attention to the subject, it appears to me very doubtful whether the case has been fully, if correctly, stated.

UPON THE MAKING OF CIDER.

From the London Farmers' Magazine.

The production of good cider must depend upon the description of fruit of which it is made, the season and state of the apples when they are crushed, and the management of the juice whilst it is fermenting. It will therefore be proper to consider the subject under these three heads separately:—

The kind of apple which makes the best cider.—The acid which gives the peculiar quick and sharp feeling upon the palate in good cider, having been first noticed in the apple, although it exists in many other fruits, has been termed the malic acid. It may not be too much to say, that it is the due combination of this acid with saccharine matter, namely, the sugar of the apple, properly fermented, which are the objects to be aimed at in the manufacture of cider. In the selection of the fruit, will depend the proportion of malic acid contained in the liquor. The crab has a much greater quantity of this acid than the cultivated fruit; and generally speaking, in proportion as we obtain sweetness by culture, we deprive the apple of its malic acid. Hence, it follows that some delicious table fruits will not make good cider: this rule, however, is not invariable, as the golden pippin and some other fine apples appear to contain the proper admixture of acid and sweetness which is desirable in the liquor. Mr. Knight recommends that the different sorts of fruit be kept separate, and considers that only those apples which are yellow or mixed with red make good cider, and that the fruit of which the flesh or rind is green are very inferior; he recommends that the apples should be perfectly ripe, even mellow, but never decayed, before they are crushed. There was a curious manuscript written by Dr. John Beale, a fellow of the Royal Society in 1657, upon the subject, from which the following are extracts:—"Crabs and wild pears, such as grow in the wildest and most barren cliffs, and on hills, make the richest, strongest, the most pleasant, and lasting wines that England yet yields, or is ever likely to yield. I have so well proved it already by so many hundred experiments in Herefordshire, that wise men tell me that these parts of England are some hundred thousand pounds sterling the better for the knowledge of it." He mentions of these kinds of austere fruit the Bromsbury crab, the Barland pear, and intimates "that though the discovery of them was then but lately made, yet

they had gotten a great reputation." He adds, "the soft crab and white or red horse-pear excel them and all others known or spoken of in other countries. Of the red horse-pear of Felton or Longland, he says, "that it has a pleasant masculine rigor, especially in dry grounds, and has a peculiar property to overcome all blasts." Of the quality of the fruit he observes, "such is the effect which the austerity has on the mouth on tasting the liquor, that the rustics declare it is as if the roof were filed away; and that neither man nor beast care to touch one of these pears, though ever so ripe." Of the pear called Immy winter pear, which grows about Ross, in that county, he observes, "that it is of no use but for cider; that if a thief steal it, he would incur a speedy vengeance, it being a furious purger; but being joined with well-chosen crabs, and reserved to a due maturity, becomes richer than good French wine; but if drunk before the time, it stupefies the roof of the mouth, assaults the brain, and purges more violently than a Galenist." Of the quality of the liquor he says, "according as it is managed, it proves strong Rhenish, barrack, yea, pleasant Canary, sugared of itself, or as rough as the fiercest Greek wine, opening, or binding, holding one, two, three, or more years, so that no mortal can yet say at what age it is past the best. This we can say, that we have kept it until it burn as quickly as sack, draws the flame like Naphtha, and fires the stomach like aqua vitæ." Thus there appears a great difference between the opinions of the two men who probably paid more attention to the subject than any other; and the question naturally arises, is the cider and perry of the county as good or better than it used to be, after greater attention having been paid to the orchards? I am decidedly of opinion that it is inferior; and it was this impression which caused me to venture to call your attention to the subject. If such be the case, it is a great object to ascertain what has caused the deterioration in the liquor. I believe that it is for want of a due proportion of the peculiar acid which is found in the greatest quantity in the wild fruit; and beg to suggest whether it would not be worth while to try back, and mix a certain quantity of crabs with the fruit before it is crushed. We have many of us tasted, and all heard of, the Stire and Hagloe crab cider, both of which were so celebrated for their rich quality; and these fruits differed little from wild apples. It is known that the juice of crabs, if kept long enough, will make excellent vinegar; every housewife knows that, however sour the liquor may be at first, it will not answer for pickling, but that if kept a sufficient time, there is no better for the purpose. It cannot be supposed that one acid is changed into another without passing through an intermediate stage, and this must be the malic acid, having been converted into sugar, which it appears in the ripening of fruit it has a natural tendency to do. The object in making cider of such fruit, is to prevent the sugar when formed passing on to the acetous fermentation. A singular circumstance occurred at Baysham: a hogshead was filled with crab juice, intending to keep it till it became vinegar; but the cask was tapped by mistake, and supposed to be cider until it was all drunk, which in fact it was. Crab juice ferments much more slowly than the juice of the apple, propably owing to there not being enough sugar already formed in the liquor: but I am of opinion that if some of the heading from a cask of cider in a state of fermentation were added to the crab juice, it would ferment as readily, and clear itself as soon, as the juice of the apple. Owing to the slowness of its fermentation, it takes a great deal of time to convert the juice of crabs into vinegar; but it is found that if, after crushing them, the must be put into a cask for some days, till it heats considerably, and that if the liquor afterwards be ground with this must and pressed again, it will pass into vinegar immediately. I therefore strongly recommend a mixture of the most austere and hardest apples which can be procured with the soft and mellow fruit before it is crushed.

The best time of the year for making cider.—It has been before observed that Mr. Knight recommends the fruit to be perfectly ripe, even mellow, before it is crushed; and this can only happen late in the autumn. As it is known to be more difficult to manage the fermentation of the liquor in warm weather, it is usual to defer making cider till November and December; if, however, the liquor can be put into a cold cellar after the first fermentation is over, I am of opinion that it might be commenced earlier. The juice of unripe fruit ferments more quickly than of that which is ripe, and contains more malic acid. Where there is the convenience of a good underground cellar, the difference of temperature between that and the outward air is greater in moderately warm weather than in November; so that if the liquor were fermented under sheds, as Mr. Knight recommends (and his instructions as to the management of the cider whilst fermenting are excellent,) and as soon as fine, removed into the cold cellar, the change of temperature would be greater at the end of September than in November; and this would probably tend greatly to prevent the liquor fermenting again. If the new cider cannot be removed from the warmth of the atmosphere, there can be no question that it is better to defer the making till the weather becomes cool.

Fermentation of the juice.—The researches of scientific men, although very elaborate, have done very little in throwing light upon the nature of fermentation; it appears to partake in a measure of the vital principle; of the phenomena attending which, we know nothing. Many curious and interesting facts have been discovered during the investigation, but none of which appear likely to be of much use in the making of cider. There are three kinds of fermentation, or rather, there are some products which pass regularly through three stages of fermentation, viz., the vinous, the acetous, and the putrescent. Other substances pass at once to one or other of the latter stages; gum and water turning to vinegar without forming any spirit, and meat at once putrefying. It is not desirable that the vinous fermentation should be complete in the manufacture of cider, in which case all the sugar of the apple would be converted into spirit; this never does happen without a portion of vinegar being also formed, the acetous fermentation going on jointly with the vinous, as, when cider frets a great deal it may be very strong, but is comparatively of little value, having lost all its richness and become sour. The vinous fermentation stops naturally before it has run its course, and it is the object of the maker to avail himself of this property in the liquor, and to endeavor to prevent any secondary fermentation

taking place ; the number of schemes which have been suggested to prevent which, showing that it is the most important point to be attended to in the manufacture of good cider. I am of opinion that the 100 gallon cask is much better than larger, and that the liquor is not only more easily managed, but more likely to be good ; it may be that cider in large casks becomes stronger, but not so frequently rich, as in single hogsheads. Although it may not be apparent, fermentation commences as soon as the juice is expressed from the fruit ; and the sooner the cask is filled and allowed to remain quiet, the more regular and certain will be the process. What should we think of a brewer who, whilst his beer was working, brewed another quantity, and added the raw wort to the first ? Yet this is constantly done in filling a large cask with cider ; or even worse, for the apple juice is added cold, whereas the wort might be mixed with the beer whilst warm. It would be greatly better to keep the liquor in open tubs till enough be obtained to fill the cask, and then put it together at once. If I may be allowed to suggest an experiment, there is one use to which I should be very glad to see a large cask applied ; that is, to fill it partly with *fresh* must, and the remainder with boiling water ; the probable result would be a very pleasant and useful liquor. Temperature has much to do with fermentation, and it would be of advantage to have two cellars, one much colder than the other. If the liquor, upon pitching fine, were racked into a clean cask, and put into a cold cellar, there would be much less risk of its fermenting again. I should recommend no other liquor to be added to it ; but in order to prevent ullage, that it should be racked into a smaller cask ; the less air admitted the better, and if the cask be sound and iron bound, it may be better to close it altogether at this time. The application of cold will check fermentation immediately. I have seen liquor in a state of froth, boiling out of a large jar, suddenly reduced to a state of quiescence by pumping upon the side of the jar. This fact induced me to cause an experiment to be tried at Gayton during a very bad season for cider making, the weather being very warm : a cask of juice was rolled from the mill into a brook of cold water, and sunk by stones attached to it ; it remained in that position till nearly Christmas, and was so much better than any other made there that year, that Mr. Newman obtained double the price for that hogshead he did for any of the rest. Perfect stillness is very desirable, as motion is found to excite the acetous fermentation. A bottle of wine, attached to the sail of a windmill in motion was, after three days, converted into vinegar, although closely corked. When a second fermentation does take place in cider, there is very little hope of its being rich and good. In such case I should recommend its being drawn out into tubs, exposed to the cold as much as possible, and after being thus flattened put back into the cask, at the same time well stirring up the whites of fifteen or twenty eggs previously mixed up with a portion of the liquor ; if this succeed in fining it, which probably it will, it may then be racked into a clean cask, and closed as much as possible from the air. It is probable that a great deal of mischief is caused by some principle of fermentation remaining in the cask ; this might be prevented by well scalding before the casks are filled ; or what I think would be better, by washing out the casks with clear lime water ;—one large piece of lime put into a hogshead of water, and allowed to settle, would answer the purpose. Some brimstone matches burned in the cask would have a great tendency to prevent fermentation. I shall not say much upon the mode of crushing the apples and pressing out the juice, having had so little practical experience, but I have always thought that if the fruit were crushed between wooden rollers, and allowed to drain before being put under the stone, that the process would be much expedited, as the apples sometimes roll before the stone a long time before they are broken. In Ireland they use a press formed by a lever, which might be made at less expense than with a screw, and be more quickly worked : it is impossible the pressure can be too light at first, and it should be increased gradually as the liquor runs from the must. Two sets of bags, allowing one to drain for some time without pressure, would be an undoubted advantage.

EDWARD PRICHARD.

Ross.

MAKING DIPPED CANDLES.

From the Journal of Commerce.

The season of the year has arrived for families in the country to make up their supply of candles for the year, and as much trouble and extra labor is occasioned by want of skill, I will, in order to enable people to obviate this, give some brief directions for dipping candles.

The tallow, when melted, should be ladled into a wooden vessel of convenient width and depth, which has been previously heated by filling it with boiling water for an hour or more. Fill the vessel within an inch of the top with melted tallow, and keep it that height by adding hot tallow or hot water. By this means the candles will be kept of a full size at the top, and not taper off to a point, as is often seen with country candles.

The tallow, when used for dipping candles, should not be too hot. A temperature that will allow the finger to be dipped in without burning, is sufficiently hot, and at this temperature the candles will take on the tallow very fast. The wicks should be lowered into the melted tallow gradually, and should be lifted out of the tallow so slowly that when the bottom of the candles are clear from the surface of the melted tallow, no tallow will run off them. When the candles are raised quick out of the melted tallow, the tallow will run off the candles in a stream, whereas if the candles are raised out slowly, not a particle of tallow will fall from the candles. A few trials will satisfy any person in this matter. If the tallow is boiling hot, the wick will not take on the tallow to any considerable extent. When candles are raised out of the tallow rapidly, the candles will be large at the bottom, and the tallow will extend below the wick, so that when burnt in the candlestick a piece of the candle will have no wick in it ; and therefore, for burning, will be useless. Where persons have no suitable wooden vessel, an iron vessel will answer for a dipping vessel. When tallow has been thoroughly melted over the fire, should it be dirty or impure, throw into it, while hot, a small quantity of finely

powdered alum, and in a short time a scum will be seen rising to the surface, in appearance like dirty froth. Skim this off as it rises. This scum will rise for half an hour or more. These directions are plain and easily complied with, and one trial will be satisfactory. Persons, by following these directions, will save more than one half the usual labor of making candles, besides having better candles. I speak from abundant experience, and therefore with full confidence. E. M.

KENTUCKY BLUE GRASS (GREENSWARD, POA PRATENSIS.)

From the Nashville (Tennessee) Agriculturist.

The best time for sowing is as soon as you get ready after October, but if you sow before the middle of March, you may expect a good stand, particularly if the season is wet.

Land.—Old fields, where the sun can exert all his powers, produce blue grass in the greatest abundance, and always of the best quality. The past fall we visited Mark R. Cockrill's farm, and saw old fields on which former occupants were threatened with starvation, yielded the richest grass. It was remarkable that his mares and sucking colts, on these pastures, without grain, were fatter, if possible, than we ever saw "the noble animal" on other treatment. But inasmuch as cultivated grounds are generally used for other purposes, the beginner is informed that woodland, particularly where the timber is not too loose, will produce good grass.

Preparation.—If you intend old land for pasture, break up the fields, and sow them in oats in February. Then put ten lbs. of blue grass seed, a half a gallon of red clover seed, and if a little timothy or orchard grass be sprinkled on so much the better. The clover, timothy and orchard grass will give a quick pasture and afford protection to the blue grass till it gets a strong hold, after which no other grass can contend with it. If woodland is to be sown, take off the logs, brush, leaves, &c., and if the undergrowth could be taken out, it would be much better. After the land is cleaned, harrow it well, then sow your grass seed at the rate of ten or twelve pounds to the acre, but if you put on fifteen or twenty pounds, you will scarcely ever regret it. The rains will sufficiently cover the seed to insure vegetation.

ON GUANO.*

By James F. W. Johnston, F. R. S., &c., Hon. Mem. of the Royal English Agricultural Society.

From the Journal of the Royal Agricultural Society of England.

Of the natural occurrence of Guano.—Guano, according to Humboldt, is the European pronunciation of the word "huanu," which in the language of the Incas means dung or manure. The substance long known by this name occurs at various points along the coast of Peru, between the 13th and 21st degrees of south latitude, both on the main land and on the numerous islands and rocks which are sprinkled along this part of the shores of South America. It forms irregular and limited deposites, which at times attain a depth of 50 or 60 feet (Humboldt,) and are excavated like mines of iron ochre. It is not known to exist in any quantity north of 13° or south of 21°; though the flocks of cormorants, flamingoes, cranes and other sea-fowl (from the droppings of which it has been derived,) appear to be equally numerous along both the more southerly coast of Atacama and the more northerly shores of Arequipa.

Mr. Winterfeldt, who appears to have more recently visited the west coast of South America, has published the following additional information in Bell's Weekly Messenger of the 11th of September, 1841:—

"There are three varieties of guano—the red, the dark-gray, and the white. The first two are met with in the isles of Chincha near Pisco, at

* Perhaps some readers may deem the subject of this article, however curious as a matter of history and of natural science, of no practical value, and therefore not worth the space it will here occupy. But the subject is not only one of interest as a very remarkable, and until now unexplained, fact in natural history, but the circumstances, as now explained, throw important lights on agricultural science. That the excrement of sea-birds, a substance among the most putrescent, and consequently elsewhere of fleeting existence, should have remained in mass for ages, and in the torrid zone, was of itself sufficiently remarkable. And the fact had been of enough importance to be recorded in history, because of the immense value of the manure, and the great use made of it, by water transportation, by the ignorant aboriginal inhabitants of Peru, and by their Spanish conquerers and their indolent descendants. Added to these facts, the deposites of excrements were so enormously thick and extensive, as almost to amount to the importance of a geological formation.

It now appears that the absence of moisture (from rain) prevents putrefaction, in a great degree; and this most remarkable, because vast effect, of a well-known law of fermentation, will serve to show to farmers, in all regions, that without moisture their manure loses nothing by the sun and air. The great richness of *guano*, and its value as manure, after all the actual waste of its most volatile parts for centuries, shows strongly the great value of *ammonia*, no matter from which of the many sources it may be obtained; and the importance of preventing its waste from all manures which evolve it during putrefaction. And in addition to these general theoretical truths, of various and extensive application in practical agriculture, it *may be* that the products of this immense mine of manure in the Pacific ocean, may hereafter be brought to benefit American, as it has already done British agriculture. This may be still the more strongly counted on, now that it is ascertained that the most recent guano is far more rich than the ancient, which is what has been mostly exported heretofore.—Ed. F. R.

Iquique, and on the hill of Pica. The term 'guano of Iquique' is sometimes used from its having been first procured from the island of that name. This island is situated about 400 yards from the port of Iquique. It is about half a mile long, and about 200 yards broad; and furnished large quantities of guano for 25 years, when it became exhausted. The hill of Pica is very high, and is covered with guano down to the water's edge; while that side which does not face the sea is of sand and gravel. In this hill or rock I am informed that a silver-mine was formerly worked, but that no trace of guano was found during the excavation. The adjoining hills on either side are of sand, which is carried by the winds, and covers up the guano; to remove which the sand is first taken away, and deep excavations are made; the guano extending nearly a quarter of a league in length, and 300 *yards in depth.** It is likewise found at St. Lobos, about three leagues to the south of Pica; but, as the anchorage is dangerous, little business is done here."

Origin of the guano.—The extraordinary thickness and extent of these deposites of guano seem at first sight to throw discredit on the statement that it is altogether derived from the dung of the countless flocks of sea-fowl which frequent the islands and rocks of the Peruvian shore: yet the evidence on this point is perfectly satisfactory. The living birds still deposite the white guano on the islands to which they resort. In the isles of Islay and Jesus 20 to 25 tons of this recent guano are occasionally collected in a single season. In the island of Torrecilla the white may be seen changing into the red variety (Winterfeldt;) while, in the midst of the great accumulations of the latter kind, bones and feathers (Frezier) of birds are found, as if to remove any doubt which might still remain as to its origin. Its real origin, indeed, was well known to the government of the Incas, and its national importance fully understood. It was made a capital offence to kill the young birds on the guano islands. Each island had its overseer; and as the whole coast from *Arica* to *Chaucay*, a distance of 200 leagues, was manured almost entirely with guano, each island was assigned to a special district of the main land, and its produce was conveyed to that district alone. (Humboldt.)

It was not till the arrival of the Spaniards that the original source of the guano was for a time doubted; yet, when we consider how great a lapse of time it must have required to admit of the accumulation of the extensive beds of ancient guano still known to exist, we cannot wonder that early European visiters should have received with hesitation what we now readily admit as the true account of its origin. Of late years the increase of traffic on the coasts has disturbed or driven away the birds, and thus materially diminished in many localities the annual produce of the white or recent guano. "Since the opening of the port of Islay the birds have nearly deserted the adjacent inlets." (Winterfeldt.)

It may be further added on this point that the chemical constitution of guano has been found to be exactly such as is to be expected from the above account of the mode of its production.

Why, it may be asked, does this substance accumulate within the eight degrees of latitude above stated only, though the sea-fowl are said equally to abound beyond these limits? This question involves a consideration both of the chemical nature of the substance itself and of the physical condition of the country in which it accumulates: it will be more naturally discussed, therefore, in a subsequent section.

Effects of guano on vegetation.—It is known to have been a common practice to manure with guano as far back, at least, as the twelfth century; and the possibility of raising crops on the sandy plains of Peru is said to depend altogether on the application of this substance.* (Humboldt.)

"In a soil of remarkable sterility, composed only of white sand and clay, it is sufficient to add a small quantity of guano to be able to reap the richest harvests of maize." (Boussingault.)

"It has been calculated that from 600 to 700 tons are annually sold in the port of Mollendo, for the use of the country around the city of Arequipa. In the province of Taracapa, and in the valleys of Tambo and Victor, the consumption should be something more; as wheat, all kinds of fruit-trees and plants, with the single exception of the sugar-cane, are manured with the guano: which is not the case with the district of Arequipa, where maize and the potato alone require it. In the district of Arequipa 3 cwt. of the guano is spread over an extent of 5000 square yards;† but, in Taracapa and the valleys of Tambo and Victor, 5 cwt. are required. The land thus manured in Arequipa produces 45 for 1 of potatoes, and 35 for 1 of maize; where wheat, manured with horse-dung, produces only 18." (Winterfeldt).

In 1828 the annual consumption of white and brown guano in Peru was estimated at 600 or 700 tons in all; but this is probably now much below the truth.

These facts afford sufficient evidence of the value of this substance as a manure in the soil and climate of Peru. It has recently, however, been imported in large quantities into this country, and has already been tried upon various crops and soils, and with highly satisfactory results. Several of these results have been obligingly communicated to me; and, as the subject is an interesting one to the agriculturist, I shall insert them in the words of my several correspondents.

1. *Experiment of Mr. Pusey.*—"The guano was applied, in the beginning of July, to half an acre of ridged Swedes, at the rate of 3 cwt. to the acre, drilled under the seed. Bones, Poitevin's manure or night-soil, dung, urate, and peat-ashes, were applied at the same time on neighboring pieces of ground. The first action of the guano was discouraging; for, on one half of the ground dressed with it, no plant came up. On transplanting into the blank spaces, the seed was found encrusted with the guano, without any sign of vegetation. This ill effect might be easily

* Mr. Winterfeldt can scarcely mean that the layer of guano is actually 900 feet in thickness: it probably climbs up the mountain side so high. Pica and Iquique are both within the latitude of 21° S., the limit assigned by Humboldt.

* We have seen how it was prized by the ancient Peruvians. About Villacori this people also manured with a species of small fish, taken in great abundance on the coast.

† 4840 square yards make an English acre

guarded against. Notwithstanding this check, the piece dressed with guano now (Nov. 11) appears to be superior to all the other plots excepting that which was dressed with dung."

2. *Experiment of Mr. Love, of Castle Farm.*—"I have made trial of the guano for rape and turnips, and in both instances, I am happy to inform you, it answered my most sanguine expectations. I mixed 14 lbs. of it, in the first trial, with 2 bushels of ashes; and although the weather was very dry, I could perceive a marked difference in the growth of the plants a few days after they made their appearance. Encouraged by my results, I next mixed 28 lbs. with 15 bushels of ashes, and applied it for turnips, by sowing it on the furrow, broadcast, and harrowing it in lightly; and, as we had frequent showers at the time, the seed soon vegetated, and the plants grew away from those on each side, and were large enough to hoe 2 or 3 days before those on the land I had manured in my usual way with dung and mould. In each case I applied at the rate of 2 cwt. per acre. The ashes I mixed with it were dry, and such as we usually obtain by burning round the hedgerows and borders of our fields. I have no doubt of its being a very powerful manure; and, on very poor soils, I think I should put on 1 cwt. per acre more than I did this summer, especially if I could not procure ashes in sufficient quantities to mix with it."

3. "*Mr. Westcar, of Burnwood, Surrey*, tried 7½ lbs. upon 5 rods of land, drilled in with barley and clover. Upon other 5 rods he applied the best farm-yard manure, at the rate of 18 loads to the acre, and sowed on these an equal quantity of the same seeds. The result was—

From dung, 18 loads to the acre 1 bushel 3 quarts.
From guano, 2 cwt. to the acre 1 " 7 "

Being a saving of expense in the manure, with an increase in the crop."

4. "*Mr. Smith, of Gunton Park*, applied 4 bushels, about 200 lbs., of guano to a statute acre; and on another equal portion of land on the same field, applied 15 bushels (6 cwt.) of bone-dust. Both were drilled into the ground with the seed wheat. The guano gave 6 quarters 2 bushels 1½ peck; the bone-dust only 4½ quarters of wheat."*

5. *Experiment of Mr. Skirving, at the Walton Nurseries, near Liverpool.*—"Three plots of ground were manured respectively with guano, nitrate of soda, and farm-yard manure; and to a fourth portion nothing was applied. All the four were sown with Italian rye-grass, on the 19th of May; and all were cut on the 2d of August last. The results were as follows:—

	Tons.	cwt.	lbs.
Guano, 3 cwt. per acre	14	15	26
Nitrate of soda, 3 cwt. per acre	14	13	37
Farm-yard manure, 20 tons per acre	13	2	96
Without manure	7	0	108

Mr. Skirving adds "that the experiment was made on poor light black soil, inclining to peat. The land was first dug over, and then the manures spread on it and lightly dug in. On account of the very dry weather at the time of sowing, the seed did not come up very soon on any of the plots, but when the rain came the crop appeared; and on the nitrate of soda and guano made more rapid progress, by a great deal, than on the farm-yard manure, and continued to do so until I was obliged to cut the crop, its luxuriance being such, both on the guano and soda, that it was all down and lodged, and injured the roots.

"The second crops on these manures will differ in point of weight, I have no doubt. At present the farm-yard manure takes the lead; the guano is next; but the crop on the nitrate is by no means making the same progress.

"I have tried the guano on several other crops, in different proportions, and all prove very much in favor of its being a most valuable manure; and the produce from it, as in the case of farm-yard manure, will be in proportion to the quantity laid on—at least, as far as 8 cwt. to the acre: beyond that, I fear, it would be too powerful for any crop."*

These are all the experiments of which the results have been transmitted to me. Though they leave very much to be desired, yet they are sufficient to show—that in the climate and on the soils of England the guano is fitted to promote vegetable growth nearly as much as on the arid plains of Peru.

Chemical composition of guano.—To what cause are we to ascribe this extraordinary effect of guano in fertilizing and increasing the produce of the land? What does it contain that renders it so grateful to vegetable life? We know that pigeons' dung and the liquid manure of the farm-yard act upon vegetation almost, if not quite, as efficiently as the guano; and as this latter substance has precisely a similar origin, we can in some measure understand from analogy only, why it should be so useful as a manure. A clear comprehension, however, of the kind and extent of its action on vegetable life, and of the circumstances under which it is likely to be most beneficial, can only be obtained from the study of its chemical constitution.

The first analysis of this substance was, I believe, published by Klaproth (Beitrage, Th. iv. p. 299); the specimen having been furnished to him by Humboldt. He found it to consist of—

	Per cent.
Urate of ammonia	16
Phosphate of lime	10
Oxalate of lime	12 75
Silica	4
Common salt	0.5
Sand	28
Water and other organic and combustible matter	28.75
	100

* Communicated by Mr. Macdonald, of St. Mildred's Court, Poultry; as were Nos. 2 and 3 also.

* These experiments would have been much more valuable had the results been given in the state of *dry hay* instead of that of *green grass*. The reason of this is, that different samples of grass from the same field yield often very different proportions of dry hay. Thus 100 stones of grass, cut from each of six different half-acres—treated with different manures—in the same field, near Aske Hall, Richmond, gave respectively of dry hay 52, 53, 36, 46, 40, and 36 stones. No accurate conclusion therefore can be drawn from the weights of the green grass yielded by the several parts of a field.

The next analysis was by Fourcroy and Vauquelin (Gehlen's Jour., vi. p. 679.) Their results gave—

	Per cent
Urate of ammonia	9 0
Oxalate of ammonia	10.6
Oxalate of lime	7 0
Phosphate of ammonia	6.0
Phosphate of ammonia and magnesia	2.6
Sulphate of potash	5.5
Sulphate of soda	3.3
Sal ammoniac	4.2
Phosphate of lime	14.3
Clay and sand	4.7
Water and organic matters	32.3
	100

If we suppose the analyses equally correct, the specimens examined severally by Klaproth and by Vauquelin differed very much in chemical constitution. That of Klaproth was mixed also with one-third of its weight of sand and silica.

To a circular, recently issued by Mr. Macdonald, the following analysis is appended, but the authority is not given :—

	Per cent.
Bone earth	30½
Sulphates and muriates	3
Uric acid	15
Ammonia.	15
Other organic matter	36½
	100

This also differs materially from the other two; and, allowing for slight errors in analysis, shows that the substance varies widely in composition. It cannot fail, indeed, to vary to some extent, according to the state of decay in which it is subjected to examination.

Of the guano which has been imported into this country a box having been obligingly sent to me by Mr. Macdonald of the average quality of that which, as he states, is likely to be hereafter brought to England, I have submitted it to a chemical examination, in reference chiefly to its economical value. It is of a brownish-red color, is evidently a very ancient deposite, and has undergone much decomposition. It consists of a powdery portion mixed with lumps of various sizes. The latter, when broken, exhibit an aggregation of minute crystalline plates, are much richer in ammonia than that which is in powder, and are freer from sand and stones. When broken up, however, the lumps speedily lose their crystalline appearance, give off ammonia even at the ordinary temperature of the atmosphere, and assume the condition of the powdery portion with which they are mixed.

1. *The quantity of sand* contained in a portion of the powdery variety I found to amount to nearly 11 per cent.; while in one lump there were present 8 per cent., and in another less than 2 per cent. The sand consisted chiefly of mica, quartz, and felspar, the debris of the igneous rocks of the coast of Peru. Occasional fragments of rock occur, of considerable size also, among the guano.

2. The quantity of volatile or combustible matters, (including the water and ammoniacal salts) which are capable of being driven or burned off by a red heat is also very variable. Thus, 4 portions, taken at random from different parts of the box, lost, respectively, 23½, 46, 60, and 53 per cent. of their whole weight; leaving an ash of a white or slightly gray color. This difference is not owing to the presence of unlike quantities of sand, for the numbers above given are calculated on the supposition that the specimens were all free from sand. Thus the first specimen lost by heating only 21½; but, as it contained 8 per cent. of sand, it would have lost, as stated above, if free from sand, 23½ per cent.

In so far as the volatile constituents are concerned, therefore, the guano which comes to this country may vary in value from 1 to 3.

3. Yet the loss by heating, which is very easily ascertained, is not a true measure of the richness of the guano in ammonia and other valuable organic matters. When reduced to powder it rapidly absorbs moisture from the air. Thus, in 48 hours, a weighed portion of a lump broken into coarse powder gained by exposure to the air 2 per cent.; another portion gained in 10 days no less than 6 per cent., and after a longer time it became perceptibly moist between the fingers. This absorption of water from the air will tend not only to depreciate the value of a given weight of the guano when brought to our humid climate, but also to cause errors in the results of agricultural experiments made with different samples of the manure.

4. I have stated above that the lump guano when crushed gives off ammonia at the ordinary temperature of the atmosphere. In hot weather this may be rendered sensible by holding over it a feather dipped in strong vinegar or diluted muriatic acid (spirit of salt,) when white fumes will be perceived; or at any time by heating the guano to 100° or 150°. By this evolution of ammonia it loses both in weight and in virtue. By drying at 150° I found a lump to lose 11 per cent. of its weight, ammonia being sensibly given off during the whole duration of the experiment; yet when it was again exposed to the air it absorbed so much water as in four days to be 5 per cent. heavier than it had been before it was exposed to heat.*

This evolution of its volatile constituents by exposure to the air is well known on the coast of Peru. From the guano island near Arica such a stench proceeds that vessels are prevented by it from anchoring near the town (Feuillé and Humboldt;) while the white guano at the present day sells in the port of Mollendo at a price more than one half higher than that which is given for the dark-gray and the red. (Winterfeldt.)

I do not know in what way the guano is shipped for transport to this country; but it is certain that were it rammed hard into casks as soon as it is taken from the mine, and so kept in this country till it was about to be applied to the land, it would neither be so far deteriorated by the loss of its volatile constituents, nor increased in weight by the absorption of water.

5. The absolute quantity of ammonia contained in the guano of Klaproth and Vauquelin is not stated. In the analysis published by Mr. Mac-

* If a little guano powder be mixed in a wine-glass with a little newly-slaked lime, ammonia is immediately evolved, and becomes distinctly sensible to the smell.

donald as above given, it is said to amount to 15 per cent.* This greatly exceeds the quantity contained in the specimen examined by myself, which gave me only 7 per cent. of pure ammonia. The same is true of the uric acid, which in my specimen did not amount to 1 per cent.† In these results a certain latitude must be allowed for necessary differences, since the older the deposite, the less rich must the guano be in uric acid and ammonia.

6. An important ingredient in the guano is the phosphate of lime, and as this substance is neither volatile, so as to rise into the air, nor soluble, so as to be washed out by the rains, it is obvious that the older the deposi e and the less volatile matter it contains, the richer it is likely to be in this earthy phosphate. Supposing each specimen free from sand, &c., the analysis of Klaproth gives 14.7 per cent., and that of Vauquelin 15 per cent., while the bone-earth in the third analysis is stated at 30½ per cent.

In two portions which I examined, the phosphate of lime amounted in the one to 29, and in the other to nearly 43 per cent. of the guano supposed to be free from sand. In regard to this substance, therefore, the guano is no less variable in composition than in regard to its other constituents.‡

7. When cold water is poured upon guano a large portion of soluble matter is taken up, consisting chiefly of common salt and of various salts of ammonia, with a very little of the urate of soda, lime and magnesia. After careful washing with water and drying at 150°, one portion left 40 and another 35 per cent. of insoluble residue, consisting of phosphate and oxalate of lime with some urate and other animal matters. It is these soluble salts which act most immediately and most powerfully when the guano is applied to the growing crop. The earthy constituents, though of great importance to the ultimate growth and health of the plant, begin to manifest their influence at a later period.

8. I have not thought it necessary to determine with accuracy the relative proportions of the oxalic and carbonic acids, or of the several salts of ammonia, in a substance so variable in its constitution. In the only specimen in which I sought for it I detected no sensible quantity of potash. It is true that Fourcroy and Vauquelin found 5½ per cent. of sulphate of potash, but this can only be considered as accidentally present in the specimen they examined, since it is not easy to understand how potash should be more abundant than soda in the excrements of sea-fowl, living almost entirely upon the fish of the Pacific Ocean.

9. Finally, the variable constitution of the guano brought to this country, and now offered for sale in England, will appear by the following *general* results of the analysis of two small portions taken at random from a box containing about 20 pounds' weight. The first contained 8 per cent. and the second only 1 1·5 per cent. of sand.

1.	per cent.
Water, salts of ammonia, and organic matter expelled by a red heat	23 5
Sulphate of soda	1·8
Common salt, with a little phosphate of soda	30·3
Phosphate of lime, with a little phosphate of magnesia and carbonate of lime*	44·4
	100

2.	per cent.
Ammonia	7 0
Uric acid	0·8
Water and carbonic and oxalic acids, &c. expelled by a red heat	51·5
Common salt, with a little sulphate and phosphate of soda	11·4
Phosphate of lime, &c.	29 3
	100

On the cause of the fertilizing action of guano.—Though so variable in composition, however, the nature of the substances it appears always to contain enables us to explain why it exerts so marked an effect on the growth of plants, as well as to answer one or two other questions—in regard, for example, to the duration of its action in fertilizing the land—and to the cause of its accumulation on the coast of Peru.

1. The most important and most active ingredient contained in the decomposed guano imported into this country is the ammonia. This substance, there is reason to believe, acts in a most energetic manner upon vegetation in every climate—it is one of the most useful ingredients

* Fifteen per cent. of pure ammonia are equal to 60 of bicarbonate of ammonia, 45 of sal ammoniac, or 40 of oxalate of ammonia. As much of the ammonia in guano exists in the state of bicarbonate, I doubt if any of the specimens which come to this country can ever contain so much as 15 per cent. of pure ammonia.

† One hundred grains of guano distilled with dilute caustic potash, and the ammonia received into dilute muriatic acid, yielded, on evaporation at 212°, 21.5 grs. of sal ammoniac, equal to about 7 grs. of ammonia. The uric acid was separated by boiling in dilute caustic potash, and precipitating by dilute sulphuric acid.

‡ Boussingault, after describing the astonishingly fertilizing action of the guano on the plains of Peru (Annales de Chim. et de Phys., lxv. p. 319,) says that it consists of urate, oxalate, phosphate, and carbonate of ammonia and *some earthy salts*. This distinguished philosopher, to whom modern agriculture owes so much, inclines to the hypothesis "*that the fertility of the soil can be increased only by the addition of substances containing nitrogen.*" (ibid. lxvii. p. 16,) and therefore pays less regard to the earthy matters which may be added to the soil. We are indebted to Sprengel for illustrating the important influence of inorganic substances in *nourishing* and promoting the growth of all living vegetables.

* The results above given indicate the proportions of the alkaline and earthy salts as they existed in the ash that was left when the guano was heated to redness in the air. The chemical reader will understand that very different numbers would have been obtained had the soluble salts been separated from the insoluble before either of them was heated to redness. This arises from the circumstance that, when the crude guano is heated, the phosphate of ammonia and oxalate of lime are simultaneously decomposed, and phosphate of lime is formed, whereas, were the phosphate of ammonia previously removed by washing, the oxalate of ammonia would, by the burning, beconverted only into carbonate. With a view to a merely *economical* object it did not appear to me necessary to enter into a rigorous examination of the relative proportions of the several salts of ammonia present in such variable quantities in the guano.

in our farm-yard manures, and though writers differ in opinion as to the amount of influence actually and constantly exercised by this compound on the *general vegetation of the globe*,* they all agree in attributing to it a very beneficial action on growing plants in general, when applied to them in a sufficiently diluted state. In proportion, then, to the quantity of ammonia it contains will the value of the guano be increased, and hence one reason why the more recent varieties should be accounted the best, and should bring the highest price in the market.

2. Next to the ammonia, or perhaps equal to it in value, though in the specimens I examined very much less in quantity, is the uric acid. This substance, as it decomposes, gives rise among other products to the formation and evolution of ammonia in considerable quantity. Under the most favorable conditions 100 of pure uric acid *might* yield 40 of pure ammonia. In nature, however, these conditions probably never occur, so that during its decomposition, numerous other products containing nitrogen are formed (prussic acid among the rest,) which it is unnecessary here to specify. We know little that is certain in regard to the action of these products on the growth of plants, but the well-known effect of liquid manure, which in a state of fermentation contains the most of them, leads to the belief that they are fitted to promote vegetation.

The *fresh* guano is more valuable, chiefly because it contains more of this uric acid in an undecomposed state. We have no analyses of the recent droppings of any of the birds which frequent the shores of Peru; they would probably be found to differ in some degree, not only with the species of bird, but also with the kind of fishes on which at different seasons of the year they were found to prey. We possess analyses, however, of the excretions of other birds which live chiefly upon fish, from which we are enabled to form an opinion as to what the recent guano is likely to be. Thus Dr. Wollaston found those of the gannet, (Pelicanus bassanus,) when dry, to contain little else but uric acid, while in those of the sea-eagle, Coindet found—

Solid Excretions.

Ammonia	9·2
Uric acid	84·65
Phosphate of lime	6·13
	100

Liquid Excretions dried.

Uric acid	59
Earthy and alkaline phosphates, sulphates and chlorides	41
	100

If we compare the first of these results of Coindet with the constitution of the guano as it is imported into England, we cannot fail to be struck with the degree of decomposition which the latter must have undergone—supposing it to have originally resembled the solid excretions of the sea-eagle. The quantity of phosphate of lime in the latter, 6·13 per cent., is unusually large for the excrement of a bird; but if we suppose the recent guano in its dry state to have contained quite as much, it would require 500 lbs. of the latter to give the quantity of phosphate (29·3 lbs.) contained in 100 lbs. of a quality such as the one portion I examined, and 700 pounds to yield the quantity of phosphate (44·4 lbs.) contained in the other. In other words, from 1·5 to 1·7 only of the original organi animal matter remains in the guano, as it is imported into England. It probably retains even less, since it has unquestionably absorbed from the air a considerable portion of moisture not supposed to be present in the droppings when recent and carefully dried.

It is easy to see therefore why the *recent* guano should bring so much higher a price on the coast of Peru; why the ancient Peruvians should have so carefully collected it, and should so religiously have preserved the sea-fowl from destruction or disturbance; and why they should have left the ancient accumulations comparatively undisturbed; to be searched for and excavated in these after times when the produce of the living birds has become less abundant or is less carefully collected and preserved.*

On the other hand, in the identity of the substances contained in guano with those always found in the recent excretions of living birds, we have that evidence of a common origin—which in a previous part of the present paper was stated to lend an almost unnecessary confirmation to the evidence there adduced in regard to the source from which the accumulations, on the shores of Peru, have unquestionably been derived.

One other remark I may here venture to introduce. We are astonished—even geologists, who are familiar with extended periods of time, and are accustomed to contemplate immense results produced by the prolonged action of apparently insignificant causes—even geologists are struck with the occurrence on the existing surface of the globe of such vast accumulations of excrementitious matter: yet how are our ideas still further magnified in regard both to the number of birds necessary to deposite them, and to the lapse of time during which they must have been gathering, when we learn that what now remains is not —either in bulk or in weight—more than an eighth or a tenth part of that which originally fell from the flocks of living sea-fowl!

3. A most important part of the composition of the guano is the quantity of phosphoric acid it contains in combination with ammonia, with soda, and chiefly with lime. All plants require for their healthy growth a portion of this acid in combination with lime. All vegetable productions which unmixed are capable of feeding and nourishing animals must contain it, since from their vegetable food all animals ultimately derive those earthy and other phosphates of which so great a part of their bones consists, and which

* The prevailing views on this subject, and the reasons on which they are founded, are explained in my 'Lectures on Agricultural Chemistry and Geology,' part i. p. 248.

* The comparative value of the *recent* droppings of birds is shown by the price usually paid in Flanders for pigeons' dung. It is there employed as a top-dressing for the flax, and the dung of 100 pigeons is worth about 20s. a year for this purpose—(Sprengel.) The injurious effect of recent goose-dung arises from its falling on the grass in too concentrated a state. When diluted by a shower of rain its influence is most beneficial.

are also present in smaller quantity in their fleshy parts, and in their various fluids.

The presence of these substances therefore enables the guano to minister *to a greater number of the wants of living vegetables* than it could do were it entirely composed of uric acid or of ammonia. These latter compounds may abound about the roots and leaves of plants, and yet, if the phosphates be wholly absent, the plant which sprung up of a bright green, and shot forth with vigor, will never attain to a healthy maturity, or produce an adequate return of nourishing food.

One of the uses served by bones when applied to the land is to yield the phosphate of lime they contain to the successive crops which are grown during an entire rotation. Hence one reason why the effect of bones upon the land is in many cases found to be so very permanent. The animal matter in bone dust will decompose and disappear in great measure from the soil in one or two seasons, but the bone earth (the phosphate of lime) remains long in the land, is—in small quantity only, and therefore slowly—withdrawn from the soil by the crops and by other natural agencies. and thus may continue to exercise a beneficial influence on the fertility of the field to which it is applied for a long period of time.

The same remarks apply to guano. On an average, 150 lbs. of guano may contain as much bone earth as 100 lbs. of bones ;* and in the same proportion will its action on the land, compared with that of bones, be permanent—in so far as this ingredient is concerned.

The fact is of great practical importance. Nitrate of soda, so much used of late and so deserving of more extensive trial, may be washed out of the soil where the earthy part of the guano would remain ; it may cease to exert a marked influence after a single crop, where it is scarcely possible that the phosphates of the guano should cease to act ; and it may fail to bring to maturity crops of corn or to fill the ripened ear, when the guano would supply to the grain, among other substances, the earthy phosphates also, which the seed contains as a necessary constituent.

While then the ammonia of the guano promotes the early growth, its phosphates supply to the ripening plant the materials which are indispensable to its perfect developement. The nitrates also, like ammonia, aid in a remarkable degree the growth of the plant in its earlier stages ; but, except the potash or soda which the nitrate may contain, it can supply to the maturing vegetable none of the inorganic substances it is known to require. Unless these are present in sufficient quantity in the soil, the healthy appearance of the young plant, whether imparted to it by the agency of ammonia or by that of nitrate of soda, cannot be safely trusted to as an index of the weight of corn we are to reap, when the time of harvest comes.

4. The presence of common salt in the guano need not surprise us. It is no doubt derived from the sea, partly through the medium of the birds themselves, and partly from the evaporation of the salt spray, continually driven upon the coasts by the winds. It is variable in quantity, as we should expect from a knowledge of its origin. The beneficial effect of common salt when applied to the land has been frequently recognized in many localities and upon many soils. It no doubt aids the other ingredients of the guano in producing its full effect upon the living vegetable.

The important influence of guano, therefore, on the vegetation equally of England and of America, seems to depend upon two circumstances—1st, on its containing a well-tempered mixture of a *great number* of those substances which the plant requires for its perfect growth and developement ; and—2d, on this admixture including a considerable proportion of a substance (ammonia) which in a remarkable degree hastens the growth of the *young* plant, as well as of another (phosphate of lime) which is necessary to its healthy and perfect *maturity*.

In the arid plains of Peru, where dews are rare and rain scarcely ever falls, we can easily appreciate the value of a substance which shall make the young plant as it were rush up when a favorable day of moisture comes, shall facilitate its rapid after-growth, and shall supply the materials necessary to its perfect maturity ere the burning sun and parching winds have time to scorch and wither it. Useful as it is likely to prove in our climate, therefore, the beneficial effects of guano may never be so striking in these latitudes as they have long appeared on the shores of Peru.

The cause of its accumulation on the coast of Peru.—Connected with this last observation is the explanation of the accumulation of the guano on the coast of Peru. I have already stated that, according to Humboldt, it is met with only between the 13th and 21st degrees of south latitude, though the sea-fowl are equally plentiful both to the north and to the south of these parallels. The explanation of this apparent anomaly is to be found in the climate of this part of South America.

Nearly the whole of the land along this coast, between the Cordilleras and the sea, is one continued desert. "I have always," says Mr. Darwin,* "applied the terms barren and sterile to the plains of Patagonia, yet the vegetation there can boast of spiny bushes and some tufts of grass, which is absolute fertility to any thing that can be seen here," (the neighborhood of Copiapo.) "In Peru real deserts occur over wide tracts of country." "It has almost become a proverb that rain never falls in the lower part of Peru." "That much rain does not fall is very certain, for the houses are covered only with flat roofs made of hardened mud ; and on the mole (at Callao) ship-loads of wheat were piled up, and are thus left for weeks without any shelter."† "The town of Iquique contains about 1000 inhabitants, and stands on a little plain of sand at the foot of a great wall of rock 2000 feet in height, which here forms the coast: the whole is utterly desert. A light shower of rain falls only once in very many years ; and hence the ravines are filled with detritus, and the mountain sides covered by piles of fine white sand, even a thousand feet high."‡

It is the dryness of the climate then which has permitted the guano to accumulate on these coasts. When we reach a region in which from

* Four cwt. of guano as much as 7 bushels of bones, supposing the guano to contain about 35 per cent. of phosphate of lime, which is less than the mean of the specimens I examined.

* Researches in Geology and Nat. History, p. 428.
† Ibid. p. 446. ‡ Ibid. 442.

local causes the dews are heavier and the rains more frequent the accumulation ceases. Cold water, we have seen, dissolves at least three-fifths of the guano in the state in which it reaches us. A single day of English rain would dissolve out and carry into the sea a considerable portion of one of the largest accumulations; a single year of English weather would cause many of them entirely to disappear.

When the recent guano falls it gradually dries and undergoes a partial decomposition. When it is again moistened by an unusual dew, or by an accession of spray driven by the wind, it again suffers a further partial decomposition, till at length it has given off, as the ancient red guano appears to have done, from five-sixths to nine-tenths of all the organic matter it originally contained. Mr. Winterfeldt states that this ancient guano is found buried beneath layers of sand; and Iquique is mentioned as one of the spots where the guano occurs. At this place, according to Mr. Darwin, the drift-sand climbs up the mountain-sides in great piles to the height of even a thousand feet. This, doubtless, is the sand beneath which the old droppings of the sea-fowl have been gradually buried; and to this ancient superficial covering it may be owing, that the buried masses still retain so much of their original organic matter. Even in that dry climate the time would at length arrive when the guano, long exposed to the agency of atmospheric causes, would retain only its earthy and non-volatile saline ingredients.

(*To be continued.*)

THE FALSE PRETENCES OF THE BANKS OF PREPARING TO PAY SPECIE, AGAIN EXPOSED.

From the Bank Reformer.

In the pamphlet on the "Abuses of the Banking System," and also at page 3 of the Bank Reformer, there were presented general statements, copied and digested from the official reports of the banks of Virginia, which showed, as clearly as facts and figures *could* show, the truth of what we had been continually setting forth, to wit: that the banks were *not preparing to resume specie payments*—nor even approaching the state of readiness to pay, by the only possible means of getting ready, which are, *reducing their loans and circulation, and increasing their specie.* The reports of the three principal banks of Virginia, and their branches, showing their condition on July 1, 1841, (published at page 3 of the Bank Reformer) showed that their condition was worse then than 6 months before. And the reports of January 1, 1842, just published, show that their condition, in comparative amounts of means and liabilities, continues much *worse* than on January 1, 1841, after another year of suspension, and of *pretending* to prepare to pay specie. The table below embraces only the three principal banks of Virginia and their branches. The reports of the small western banks have not been yet published. It is presumed however that these now presented, make at least as good an exhibit as the smaller banks, not here embraced.

TABLE, SHOWING THE COMPARATIVE CONDITION OF THE BANK OF VIRGINIA, FARMERS' BANK OF VIRGINIA, & EXCHANGE BANK OF VIRGINIA, ON JAN. 1, 1841, AND JAN. 1, 1842,

In regard to their respective rates of outstanding debts, circulation, and specie.

	OUTSTANDING DEBT.		DIFFERENCE	AMOUNT OF SPECIE.			NOTES IN CIRCULATION.		
	JAN. 1, 1841.	JAN. 1, 1842.		JAN. 1, 1841.	JAN. 1, 1842.		JAN. 1, 1841.	JAN. 1, 1842.	
BANK OF VIRGINIA,	5,271,538 08	5,352,713 89	INCREASE. 81,175 81	901,021 66	824,110 02	DECREASE 76,911 64	2,798,385 43	2,790,195 76	DECREASE. 8,189 67
FARMERS' BANK,	4,780,696 83	5,026,402 84	INCREASE 245,706 01	686,262 08	764,798 23	INCREASE 78,536 15	2,295,820 50	2,666,278 50	INCREASE. 370,458 00
EXCHANGE BANK,	2,068,975 06	2,409,555 80	INCREASE 340,580 74	277,502 15	248,256 41	DECREASE 29,245 74	703,860 00	722,575 00	INCREASE. 18,715 00
			Total Increase. 667,462 56			Total Decrease. 27,581 23			Total Increase. 380,983 33

The proportion of circulation to coin, in the said banks, in 1841 and 1842:

	Jan. 1, 1841.	Jan. 1, 1842.
Bank of Virginia,	$3.10 to $1 coin.	$3 38 to $1
Farmers' Bank,	3.34 to 1 "	3.50 to 1
Exchange Bank	2.53 to 1 "	2.90 to 1

From the above statements, made from official reports, it therefore appears that the three great banks of the state have, during 1841, (on an average,)

Increased their outstanding debts	$667.462 56
Increased their circulation,	380.983 33
Decreased their specie,	27.581 23

Nothing can possibly more plainly show, than these and earlier comparative statements which we have before published from the official reports of the banks made by their own officers, the inconceivable folly and stupidity of those persons who yet continue to believe that the extending the times of indulgence to suspended banks will have any effect in causing the banks to *prepare* to pay specie. Such stupidity in believers can only be equalled by the unblushing falsehood and knavery of those who *knowing the falsehood and absurdity* of such pretences, continue to urge the enactment of extended indulgence to bank suspension of payments, *as the proper and sufficient means of the banks' preparing to pay specie.* We have, for the last year, been telling the self-evident truth on this head, but it was to the ears of those who would not hear—and laying it before the eyes of those who would not see, even if the truth were as manifest as the noon-day sun. We have no hope now of inducing many to mark what we now again set before them, though it be taken from the reports of the banks themselves.

But though figures, in these condensations of statistical and official reports, show at a glance the general and important truth that we have tried so much and in vain to establish, there is no need to resort to such testimony, for the purpose of knowing that such *must* be the result, from the nature of things and the nature of man. The directors of banks, and those who most influence directors, have every operating inducement, of interest and feeling, to keep the banks *unprepared* to resume payment; and no inducement whatever to make preparation, save the mere cold and feeble dictates of right, justice, and moral obligation, even if these were not generally and entirely obscured and silenced, by the stronger promptings of interest and feeling. The greater number of bank directors, are also regular *borrowers*, and the *largest* borrowers from the banks. Though they take the lion's share of the loans, they cannot take *all*; and therefore, that they may get as much as possible for themselves, they are obliged to let other claimants be also supplied. Thus, while avarice urges them to continue expansion to supply their own wants, and, as an excuse for this, to supply the demands of other borrowers, the whole procedure is concealed under the plausable disguise of friendly sympathy for the wants of individuals, and of a public-spirited sustaining of the trade and business and general weal of the community. Again—to keep the banks totally unprepared to meet specie payments, and to keep the greatest number of debtors in the greatest possible danger of ruin, by sudden and heavy demands for payment, is the condition of things which serves precisely as the great and always unanswerable argument to the legislature to postpone for another year the resumption of payments—as resumption must always be disastrous to the banks and to their debtors, if commenced when totally unprepared for, either by the banks or by their debtors.

If, then, there were no other reason whatever operating on bank directors, and the borrowing class which control directors and banks, and all others who likewise desire the continuation of suspension, would they not certainly endeavor to maintain (as they do) the state of total *unfitness* of the banks to resume, as the sure means of obtaining further indulgence for continued non-payment? The idea that extending to the banks the time of indulgence of non-payment will alone serve to induce them to make preparation to pay, is so absurd and ridiculous, that no intelligent man, but a bank director, or a bank borrower, would have the hardihood to assert it, or to pretend to believe it *himself*, unless to convince an auditor deemed stupid enough to be imposed on by the grossest possible delusion.

In conclusion—we repeat, that if it be honestly desired by the legislature to compel the banks to return to specie payments, the only and the certain means will be to STOP THEIR MAKING LOANS, as well as declaring dividends. If this had been done in 1837, with a very slow and lenient curtailment of the existing debts, the banks would have resumed specie payments in two years at farthest, and might now be in as sound condition as the banks of South Carolina, which are all specie-paying, and in good credit. Even now, though nearly five years have been lost to this object, by foolishly or knavishly leaving it to fraudulent banks to stop their own legalized and profitable frauds, yet even now, if this policy were adopted, it would bring about specie payments in less than a year, and much sooner than any other legislative requisition and penalty whatever. And without thus stopping or greatly limiting of loans, the banks of Virginia *never will* pay specie, until forced into liquidation, or driven by general want of confidence into avowed bankruptcy.

IRISH POTATOES FROM SEED.

From the London Farmers' Magazine.

Squeeze the mucilaginous pulp with the seed out of the "apples" into a basin containing a weak solution of soda or common potash (lukewarm,) when on stirring the mixture, the mucilage will dissolve, and allow the seeds to fall to the bottom; they may then be drained or strained out, and washed in clean tepid water—strained again, left to dry on a cloth, and hung up in paper bags to the kitchen ceiling till March, when they may be sowed in beds of light rich earth, prepared in the usual way for small seeds. The writer found it the best way to sow them in drills at one foot asunder, for the convenience of weeding, &c. They should not be sown thick; they will grow very freely. When the leaves and stalks are all withered (the early kinds will be months before others) they must be taken up and preserved in boxes of sand, or very light, dry earth, till the following spring, when they may be planted (whole) in small drills in the usual way, about 1½ or 2 in-

ches apart in the drills. With proper attention they will attain a good size; and when gathering, can be sorted and named according to fancy, as there will be a numerous variety. The earliest kinds, will be first withered, the later ones generally attain a larger size. W. C.

REMARKS ON THE AGRICULTURAL SOCIETY OF THE UNITED STATES.

To the Editor of the Farmers' Register.

February 9th, 1842.

In publishing the constitution of the "Agricultural Society of the United States" and a list of its officers, I perceive that, although you say "*you shall heartily rejoice*" if "*your anticipations and fears*" of its failure "*should prove to be unfounded*," you have added an argument against the plan, which, notwithstanding its brevity, will as certainly prevent such hearty rejoicing from ever taking place, as if you most anxiously desired to defeat the project altogether; that is, should this argument have the same effect on the minds of others which it has produced on your own. Indeed, I cannot even imagine any more effectual way fairly to kill any scheme which depends upon public opinion, than publicly to use the strongest reasons we can think of against it. Your argument, concise as it is, not only gives the substance of all the most plausible objections which have been urged against this society, but you have much increased its force by pronouncing the plan to be "*ambitious*." Now if this be true of the plan, it must be equally so of its authors; and must utterly condemn both in the minds of all who affix the same meaning to the term "*ambitious*" that I do.

It is at all times a matter of so much regret with me, where I find we differ in regard to any of the means for promoting the great cause to which we have both devoted ourselves, that I would never express such difference, unless urged to it by some motive much stronger than ordinary. True it is, that we have very generally concurred in our opinions relative to those means; and therefore it increases my present regret to perceive how widely we differ respecting the "Agricultural Society of the United States." But, connected as I am with that association, I feel it to be my duty to endeavor to refute the arguments which you have urged to prove that "it can not possibly *work right*." Your first objection is in the following words: "It cannot be expected that any considerable number of individuals, or enough to maintain even the semblance of a United States Agricultural Society, can be induced to travel to Washington, from all the states of the union." This objection would have some force, if any such expectation had been expressed, and its realization relied upon as essential to the maintenance of such society. But not having heard of any thing like it, I cannot believe it ever entered into the heads of any of the contrivers of this "ambitious plan," (if you will have it so,) that some members "*from all the states of the union*" must always attend, "*to maintain even the semblance of a United States Agricultural Society.*" Such attendance you call "*incredible sacrifices*;" but admitting the bare possibility of their being made, you ask, "what could be expected from their meeting, more than the usual and almost useless procedure of agricultural societies in general?" I will readily answer, not much more truly, if "*agricultural societies in general*" (of which we now have some hundreds, I believe,) were indeed the "almost useless" things which you here affirm that they are. But we have sanguine hopes that more, much more *may* and *will* be done; for we cannot discern the same difficulties that you see, in the way of its accomplishment. None of us deem it necessary to success that "*members from all the states of the union*" should attend, since we know that there are at least two large societies embracing all the states of our confederacy, which have been flourishing for many years, without any such general attendance. I mean the American Bible and Missionary Societies; not that I would compare these noble associations with ours in point of utility—far from it; but I mention them solely to prove that large societies, even more comprehensive than ours, may and do succeed to a very great degree, although but partially attended by their members. All that is necessary is, that there should be sufficient intelligence, zeal, and activity in a few to devise and direct their operations; and that funds enough should be contributed to accomplish such of their purposes as require money to achieve them. Such funds have always been collected by the societies referred to, without the personal attendance of more than a few, comparatively speaking, of their contributors, and they have also been applied in a way, not only to do great good, but to be approved by the absent as well as the attendant members. There cannot, therefore, be any reasonable doubt, but that our society might flourish in the same manner, and by similar means, even although its meetings were attended only by a small portion of its members compared with the whole number.

There is, however, a moral certainty that these meetings never will be small, if held, as we design to hold them, during the sessions of congress; for many of the members of that body are also members of the Agricultural Society of the United States; and it can hardly be doubted that numbers of persons from the adjoining states will also attend, more than enough altogether to carry on the business of the society quite as efficiently as any institutions of the kind in our country have carried on theirs. But time alone can prove whose anticipations are correct, yours or mine.

That such an agricultural society, as you imagine could possibly be formed in the District of Columbia, might be there established, I presume no one can doubt who has any knowledge of its citizens. But if these associations have so wofully failed, as you say they have, almost every where else in the United States, there surely is but little probability that one would do any better in or about the city of Washington. Admit, however, that it would, and that it succeeded far beyond any which has ever yet been established among us; there are certain things all-important to the general improvement of American husbandry, that no local society whatever could possibly achieve. These are, first, to form a body of husbandry for the whole union, by collecting and publishing all that is at present known and most approved throughout the different states, in every branch of rural affairs. This important duty will

be assigned to the vice-presidents of the society, and so far as I have any knowledge of the gentlemen already appointed, none are more capable of executing this duty well. A single report from each in regard to his own state would at once effect the object, after all were properly collated and arranged for publication; and annual reports afterwards would make public all the improvements which are constantly being made throughout our country, and which in no other way, probably, could so soon, (if at all,) become generally known to the whole body of the yeomanry of the United States. If the vice-president of any particular state should not possess all the requisite information, it is presumable that he could readily obtain it from the district and county societies which, I believe, are now established throughout the union, and whose members, in all probability, would take peculiar pleasure in furnishing it, when they knew the highly important and national purpose for which it was sought.

The second great object which our society will endeavor to accomplish, and which no local society can possibly effect, will be to ascertain, by fair and full trials, the comparative merits of all the most approved machines and implements used for the various purposes of husbandry; and then to make the results as public as possible. This would soon have the effect of checking, if it did not entirely stop the sale of the numerous "catch-penny" things, which their owners, at present, very often succeed in selling throughout our country, to the immense injury of ignorant purchasers; for the awards of such a society would, in all probability, be deemed the best attainable evidence of merit or demerit in all such articles, by every person who saw them for the first time, and of course could know nothing of their real value.

In the last place, such a society as ours, however partially attended, would certainly make our brethren, in the distant parts of our confederacy, sooner and far better acquainted with each other, than any other means that are at all likely to be resorted to; and would thereby contribute much towards strengthening those bonds of fraternity, the preservation of which is absolutely indispensable to the welfare and happiness of the United States: without those ties our union must prove nothing better than a "rope of sand."

These, my good sir, are my principal reasons for differing from you so entirely in regard to the Agricultural Society of the United States. They are the result of long and most deliberate reflection, made, too, many years ago, and before I had any the slightest expectation that such society ever would be formed, or that I should have any office in it. Of course, no "*esprit du corps*" has dictated them. Time alone (as I said before) can prove which of us is right—you or I. But of one thing I feel quite as certain as if it had actually happened. It is, that if your anticipations and fears should prove unfounded, however "heartily you may rejoice" at it, you cannot possibly do it more than will your old friend,

JAMES M. GARNETT.

[We were reluctant to express the opinions which are here censured by our highly esteemed friend and correspondent, and will not add a word of replication, nor say any thing in reference to the opposite views presented above. We will merely repeat, that we shall not only rejoice, but shall be ready to acknowledge our error, if the anticipations should prove false, which, being entertained, we thought truth and candor required us to express; and which were desired to be expressed in terms the most respectful, as truly felt, for the members of the society.

The application of the term "ambitious" to the plan of the society was by no means meant in an offensive sense, nor supposed obnoxious to any such construction. It was used merely in regard to the very wide ground and sphere of operations assumed by the society; and such ambition was noble and praiseworthy for its motives, even though the practical course might prove to be injudicious and inefficient.—ED. F. R.]

HINTS AND OBSERVATIONS.

For the Farmers' Register.

Raising of lambs.—Build a pen upon the plan of a pig pen. Leave a hole for the lambs to enter. Have a trough to put bran or meal in. It will be necessary for you first to catch the lambs, and put the bran in their mouths two or three times. They will learn to eat when five or six days old; and at the time (say 15 days old) when they generally die for the want of milk, they can live without the aid of the mother. I have had them to run in as readily as pigs.

All stock ought to be housed. They will make much more manure, and live upon about one half the food.

Sheep.—The Merino sheep, with a mixture of the long wool, is best for family use.

Cattle.—A small cow can live well upon long or short grass; but a large one cannot prosper upon short grass.

Tobacco, I think, is not as great an exhauster as corn, the roots running much deeper, and fewer near the surface.

Hemp is a very profitable crop. It will grow, upon good land, from 7 to 12 feet, and is considered an improver.

Flax is an exhauster, but a profitable crop. I have known, from two bushels' sowing, between 30 and forty bushels seed made, worth $1.25 per bushel, and 330 pounds of flax from the swingle, worth 10 cents per pound.

The oat crop is considered injurious to sandy lands, but the clay soil seems to be benefited by it.

Buckwheat is considered a very uncertain crop, at times very productive, and a great exhauster of lands.

The turnip is considered a productive and beneficial crop, but the greatest exhauster of any thing sown upon the soil.

Grasses.—The herds-grass is better adapted to wet land, and also upon high sandy land, than any other I have tried.

Timothy will make the heaviest crop of any grass upon moist land, and grows well upon high manured land.

Orchard grass grows luxuriantly, and I consi-

der it the best grazing grass that I have ever seen.

Wheat sown out of season.—I sowed in my garden a peck of the Baltimore bearded wheat, about the first of April. There were a few indifferent heads in July or August. I let it remain. It lived over the whole summer, which was dry, and I cut it the next 4 h of July, as good wheat as you ever saw, but not so thick.

Prince William, Va. R. FOSTER.

COMMENTS ON ARTICLES ON BERKSHIRE HOGS.

To the Editor of the Farmers' Register.

I have thus far stood aloof from the controversy, which has been going on between the breeders of the different kinds of hogs, which they are anxious to put off upon the public. Perhaps I ought to pursue the same course still. But there are certain communications in your last (January) number, which I think ought not to be passed over without comment. And here let me assure your readers, that I do not undertake this thing in the spirit of controversy. I shall take sides with neither party. My sole object is to correct certain mis-statements or *mistakes*, if you choose, which, in my opinion, are calculated to mislead the public.

On p. 30, a writer, whose signature is R. S. B., uses the broad assertion, "that the Berkshires are not what they are cracked up to be." And in proof goes on to assert, "I have a neighbor who has given them a fair trial, to which I have been an eye-witness. The experiment was made in this way:—two Berkshires were placed in a stable with two of the common breed, all of the same age, and were carefully fed, and at the end of nine months were killed, and the result was, that the common breed exceeded the Berkshires in weight, one fifty and the other sixty pounds." Here it must be admitted, is a very formidable assertion. But without intending to impeach R. S. B's. candor, I must say that the trial was by no means "a fair one." Every one must have observed the difference in thrift of hogs of precisely the same breed. And even in the same litter of pigs, there is often the most striking difference, some growing off rapidly, whilst others are puny and weak and not worth raising. Now, in the present instance, all that we are told is, that the hogs were equal in numbers, equal in age, fed the same length of time and on the same food, and that at slaughtering the common hog greatly exceeded the Berkshire in weight. Now, without calling one of these facts in question, allow me to inquire, may not the increased weight of the common hog be accounted for, on some other principle than his superiority? Perhaps he may have been more healthy, and therefore more hearty; perhaps the Berkshires were stinted when young, a misfortune from which they never recover; or I can conceive twenty other *perhapses* on which I can account for the difference. But I have already alluded to a litter of pigs, in which there is no difference in breed, but still a great difference in thrift. Now, when R. S. B. will account for this difference, I will do the same in his case.

But R. S. B. presents another formidable objection to the Berkshires. "They are not prolific: a gentleman of my acquaintance had four sows, each of which had but *one pig*, being a loss of at least ten per cent. a head, and the generality of them, I believe, do not get more than four or five." This objection, I confess, somewhat surprises me. I really know not what to make of it. The Berkshires have hitherto been considered as *remarkable* for their prolific qualities, and my own observation has confirmed the fact. One of my boars got on a neighbor's sow fourteen pigs, on another nineteen, and on a third, twenty-two. And in my own case, my sows breeding from this and another boar, have so many pigs, that I am constantly subjected to the painful necessity of killing them, to prevent worse consequences. I have always thought a bet a very poor expedient to establish any fact. It only proves the sincerity and confidence of the party. And as this is what I have principally in view, I hereby offer R. S. B. not a *bet* but a *barter*, that for every Berkshire sow, young or old, he can find having but one pig, I will find twenty that have five or more; and for every full grown sow, that has only five, I will find fifty that have ten or more.

There is another communication in your last number, p. 12, signed Bolling Jones, which I think requires some notice, not that it contains any mis-statements or even mistakes, but because it makes a representation which is calculated to discourage the raising of pork among us. This gentleman's hogs, it seems, cost him $22.42½ when the same amount of pork might have been bought for $14.96. Here is evidently a great loss. But let me inquire, in my turn, what line of business, in all or any of the pursuits of life, is at all times exempt from losses? Would it be considered as wise in the merchant, the mechanic, the manufacturer, or any other person, to abandon a pursuit usually profitable, simply because he had met with a loss? On this plan all trades and pursuits would be subjected to fluctuations and changes, which would eventually destroy the whole. The fact is that the last pork season was a very unusual one. I cannot call to mind the time when pork was so cheap. A variety of concurrent causes served to depress this article to a degree never known before. If Mr. Jones could have bought it last year for $4, he knows that the usual price in his county has been $6 and sometimes more. If therefore pork had continued at its customary price, a price which it will in all probability recover again, there would have been no loss even in his case. And here let me remark, that the sure and direct mode to raise the price of pork, is to do just as this gentleman has done: abandon the raising of it himself, and discourage it as far as he can in others also. If this state of things become general, we shall soon be without hogs of our own, and then the Kentuckian will charge us just what he pleases for his.

But Mr. Jones, according to his own showing, has subjected himself to full twice the expense that there was any need for in raising his hogs. His hogs, it seems, in 15 months and 5 days, "each ate 37 bushels 1½ peck of corn." Now I affirm, and that too upon actual trials, amounting to many hundreds, that 11 bushels of corn, with such other food as every farm will produce, is sufficient to keep a hog in good thrift for the first

12 months of his life, and then to fatten him in the bargain. And this I say, not from the report of a servant, but, being my own hog-herd, I know it to be a fact. This subject has already been presented in detail by me, and published in the October number of the Southern Planter, to which I refer Mr. Jones and all others who may be curious about it. I would just remark, that his great error seems to be that he had corn, and scarcely any thing else for his hogs, and hence his great expense in rearing them.

But, Mr. Editor, before I leave this subject, I have a word to say to *you*, and this in fact was my chief reason for taking up my pen at this time. At the end of Mr. Mahard's communication, page 17, you have appended a note, in which you *seem* to discourage the strenuous efforts which are now in progress to improve our stock. I say *seem*, for I cannot believe that a man who has done so much for the improvement of the soil as you have, would designedly throw one single obstruction in the way of improving our stock. In this note "humbug, humbugging, humbug forever, deception" and such like, frequently occur, as connected with this subject. Now, although I am free to admit with you, that many impositions have been practised in this matter, yet I am by no means prepared to concede that *all* is humbug and deception. I believe that among those who have imported fine animals, with the view of propagating and selling them, are many as honest, as high-minded, and as much above the meanness of deception, as any class of men whatever. I will even go further, and say, that these United States owe to these men a debt of gratitude, which they will find it very difficult to extinguish. These, I doubt not, are your sentiments as much as they are mine. Why, then, allow me to ask, cast ridicule upon a whole class of men, when comparatively few deserve it? But, sir, improvements are certainly in progress, and no representations of humbuggery, by *implication* or in any other way, can possibly arrest them. Men will see for themselves, and when the fact is obvious, they will not allow it to be controverted. When I was a boy, my father had the good judgment and kindness to require me to hold the handles of the plough. But after I commenced my little education, I knew nothing practically of this implement for about 20 years. At the expiration of this period, it was my good fortune to return to the plough again. I only regret that I did not return much earlier. But when I came to my old acquaintance, I was literally astonished at the improvement which had been effected in it. Instead of that little unsteady thing which merely *scratched* the surface, I found a solid implement, which took a firm hold on the soil, and completely inverted the sod. With this practical evidence before my eyes, and in my hands, could I doubt that an improvement had taken place in the plough. In the same manner, some years ago our hogs were a long-snouted, lank-sided, long-legged, ugly beast, requiring two or three years to get their growth, and a poor affair even then. Now I see an animal compact in form, having a large proportion of body, with leg just enough to take the necessary exercise, but not enough to fit it for mischief, and giving me more meat, and better meat, in 12 or 18 months, than the old hog did in twice that time. And shall I not call this an improvement? *You*, sir, in your zeal to prevent imprositon, may call this humbuggery; but I call it solid improvement.

Notwithstanding what I have said, I cheerfully acknowledge that the public has been sadly gulled on this subject. I doubt not that in some instances, when Brother Jonathan was hard run for a genuine pig, and strongly tempted by the $10 jingling in his hearing, he was prevailed on, *just this one time*, to send a [low] grade pig. In other instances, when there has been honesty enough to send the genuine, the inferior have been selected for this purpose, whilst the best have been kept at home. These are the cases, sir, which you so justly and severely reprehend. But in the midst of all these spurious coins, there is certainly some genuine metal; and this is all that is contended for by your humble servant,

J. H. Turner.

QUERIES IN REGARD TO PREVALENT DISEASES PRODUCED BY LOCAL CAUSES.

The following queries were drawn up at first for the consideration of the Board of Agriculture. But they were not offered by the writer, because he deemed it injudicious, at the outset, that the subjects of inquiry should be more extensive than those actually adopted by the Board. But there is no subject, not strictly belonging to practical husbandry, which has a closer relation to the interests of agriculturists, through a large part of Virginia, than the investigation of the sources of malaria, and its effects, and, by ascertaining facts, to discover any means for the prevention or mitigation of this scourge and destroyer. To invite attention to the investigation, and the furnishing of accurately observed facts, these queries are here submitted in their original form, to serve merely as suggestions. Nearly all men of observation and experience who reside in lower and middle Virginia, though knowing nothing of medical science, have by observation learned facts which would throw some light on this dark subject; and still more could be done by country physicians possessing also equal means for observation. Any accurate facts furnished on this subject we would gladly publish; and whether few or many, they will, according to their extent, form useful materials for future and more extended labors of the Board of Agriculture. We have long been convinced, and have stated the grounds of the conviction, that much of the production of the baleful effects of malaria may be prevented by a proper system of agriculture, aided and enforced by legislative enactments and strict police; and that such a system would be profitable of itself directly, and ten-fold more profitable indirectly, as serving to

lessen the losses and pain and unhappiness produced by disease and death.—Ed. F. R.

1. Is your region or neighborhood subjected to autumnal fevers, (the effects of malaria,) or any other diseases produced by local causes—and, to what extent and degree, in general?

2. What are the supposed local causes or particular sources of malaria, and their comparative injurious power—as rapid rivers and smaller streams sometimes overflowing the bordering low-lands, tide-water marshes, salt or fresh, swamps, mill-ponds, and the passage of floods from mill-ponds, at uncertain and irregular times, over salt tide marshes?

3. Have diseases from such causes increased or diminished in frequency or virulence within any certain past time, and if so, to what circumstances are the changes ascribed?

4. Can the lessening or removal of malaria and its effects be effected by the action of the residents, either operating alone, or necessarily requiring new legislation, or general police, in regard to drainage, mill-ponds, removal of nuisances, &c.?

5. In illustration, and as proof, state particularly any known facts, and the authority on which they rest, which serve to confirm the opinions expressed in answer to the preceding queries.

RECEIPT FOR MAKING SOAP.

From the Massachusetts Ploughman.

Mr. Buckminster:—I am not quite satisfied with your explanation and recipe for making soft soap. This article is a compound of potash and tallow, or grease, which union is formed in conformity with the laws of chemical affinity, and in different proportions. Whenever they are brought together in these proportions, so that their respective particles come into uniform contact, unless some counteracting substance is mingled with them, the union is inevitable and its result good soap. In order that these particles may be brought into complete and uniform contact, agitation with water is necessary.

The quantity of water required, depends on the quality of soap you wish to produce. A barrel of soap may be three-fourths water. With this quantity and the proper proportions of potash and grease, it will be very good soap. It is however more commonly seven-eighths water, and sometimes reduced much more, and then, of course, it is very inferior in quality, not that it will not do its office, and do it as well, but it does less. If this process be so simple and its result so inevitable, your correspondent wishes to know why any person who attempts it has "bad luck" and fails. There are several causes of this. A very common one is that either the potash or grease is in excess.

The former ought always to be so to some extent, to make the soap effective for cleansing whatever it may be applied to. That part of the potash which is in excess is always ready to combine with any substance which is brought into contact with it, for which it has an affinity. For animal fat of all kinds this affinity is very strong, and more or less so for all kinds of animal matter, as washwomen, who have used that which has too much uncombined potash, have often found out by its effect upon their hands. Cloth made of wool, or part wool, will be ruined by it—the affinity of potash and wool being such, that a very good soft soap can be made of them.

On the other hand, if the grease is in excess the soap is good for nothing; the alkali in the compound being already surcharged with grease, has no power for removing dirt, stains, &c.—while the uncombined grease defiles whatever it is applied to. As before remarked, for the ordinary purposes, for which this kind of soap is wanted, the potash should be in excess. If it is too much so, however, the soap, as the saying is, "will not come"—nor will it if the grease is so in the slightest degree. If either of these causes is operating to prevent its "coming," the best way to ascertain it is by touching the soap to the tongue. If the potash predominates to an extent sufficient to prevent the soap from coming into work, its effect upon that organ will be rather severe. If the potash is not felt at all, more lie must be added. But, as I have before intimated, there are other causes of failure besides these two. A very small portion of common, or any other kind of salt, or of any kind of acid, will prevent the combination desired. The former unites with the water, forms a brine and settles to the bottom, and on being permitted to cool, will leave a greater or less thickness at the top of an inferior kind of hard soap; according to the greater or less amount of grease used. Acid will unite with the potash—make a brine of the water which will settle to the bottom, and if there is enough of it in leave the clear grease at the top.

There is generally some salt in family grease unless it has been boiled upon water. Sulphate of lime or magnesia is in some wells so abundant as to render it impossible to make good soft soap with the water. The sulphuric acid of these substances having a stronger affinity for potash than for these, leaves the latter, unites with the former, and forms a salt called sulphate of potash, which being dissolved in the water forms a brine and settles to the bottom.

Again, carbonic acid, (a gas,) which is constantly floating in the air, has a strong affinity for potash, and when united with it forms a salt (pearl-ash) which will prevent soft soap from "coming." This union is constantly going on with the potash, even before it is leached from the ashes, so that if they are very old, so much of this kind of salt is formed that unless it is in some way removed, soap cannot be made of the lie. For the same reason old potash, which is on the outside of the lump, where the air has come into contact with it, will be pretty sure to disappoint the expectation of the soapmaker. This difficulty, which always occurs to a greater or less extent, must be removed, and for this purpose (not, as you seem to intimate, for "its strength") lime is used, it having a stronger affinity for carbonic acid than potash has. Consequently when they are brought into contact, the acid leaves the potash—combines with the lime and forms an insoluble substance called carbonate of lime, and is simply pulverized limestone. There are other difficulties in the way of making this kind of soap in Boston and vicinity. Coal ashes produce no potash. The same is the fact with turf or peat

ashes. Nor have the ashes of rotten and decayed wood any of this substance in them, while that which has been soaked in sea water has a portion of salt among its ashes.

One word by the way of a recipe or process in conformity with these facts.

In preparing the ashes for leaching about one peck of unslaked lime, after being slaked and completely pulverized, should be mingled and equally mixed with three bushels of good ashes, damped enough to prevent dust from rising. In this way, as you will perceive, the lime and potash come into close contact with each other, as soon as the latter is drawn from the ashes by the water which is applied for leaching them, and therefore the acid has the best possible opportunity for coming in contact and uniting with it. Lime placed at the bottom of the leach, by itself alone and unmixed with the ashes, will do the lie a great deal of good by attracting much of its acid, as it passes through, though much less than when mingled with the ashes throughout equally. Placing it upon the top of the leach is almost useless. Water can dissolve only about 1.500 part of its weight of lime; and only that lime which is dissolved while the leaching water is passing through it comes at all into contact with the potash. To put lime into the soap is much worse than useless.

Nor am I quite satisfied with your leach tub. It should be perfectly tight, with but one hole in the bottom for drawing off the lie and that as carefully stopped as your cider barrel until your lie is fit to draw off. A board with a dozen inch holes bored through it, resting upon bricks edgewise and covered half an inch thick with shavings makes a good bottom for a leach tub.

The ashes when put in should be crowded and trodden completely together, leaving about three inches of space at the top of the tub for receiving the water.

After filling in water until the ashes will take no more, it should be permitted to stand 4 or 5 hours to allow the lime an opportunity for combining with the carbonic acid. The lie is then to be drawn off, and so much of it as is under the false bottom, or between that and the ashes, should be again put upon the top of the leach, that by a second passage through the leach it may be made perfectly caustic.

Your mode of testing the strength of the lie is as good as any, unless an instrument called an alkalimeter is at hand. Lie thus made, if not too strong or too weak, will be certain to combine with the grease as soon as the mixture is warm enough to melt the grease, provided it is moderately stirred, and provided the grease is pure. This may be made certain by boiling it a few minutes with half its weight of water, and afterwards letting it stand long enough for the water to subside. With 25 pounds of such grease you may be sure of an excellent barrel of soap. SOAP BOILER.

Newton, Feb. 2, 1842.

POWDER OF SLIPPERY ELM.

From the United States Gazette.

We live but to learn and obtain knowledge. Being in the country a few days since, on a visit to a sick friend, I was shown an article entirely new to me, which is said to be remarkably nutritious and palatable for debilitated and sick persons. It was flour, prepared by the Shakers from slippery elm, and used the same as arrow-root. One table-spoonful of this flour, boiled in a pint of new milk, is excellent to feed infants weaned from the breast. They will not only fatten upon it, but it will prevent bowel complaints. It makes an easy and nutritious diet for consumptive and dyspeptic persons. From the character I received of it, I presume that it only need be known to become of general use.

DRIVING CATTLE.

I have often witnessed the infliction of cruelties on dumb beasts accused of sullenness, by persons attempting to lead or drive an animal alone. This subject was brought to mind so forcibly a few days since, by a neighbor sending a boy to lead a a heifer a distance of several miles, by a rope attached to her horns and nose, that I determined to write a line upon it. The restiveness of cattle, in such cases, is caused by skittishness. The remedy is simple and efficient. Fasten a board before the face, in the usual manner of blinding breachy* cattle, and the wildest cow or heifer may be led or driven with perfect ease.—*Maine Cultivator.*

AN ESSAY ON THE SYSTEM OF AGRICULTURE BEST ADAPTED TO KENTUCKY.

By Adam Beatty, of Mason county, Ky.

[To this essay was awarded the premium offered by the Agricultural Society of Kentucky.]

In adopting a system of agriculture best suited to the circumstances of our state, regard must be had to its variety of soil and climate. The climate of Kentucky extends from thirty-six and a half to thirty-nine degrees of north latitude. So far as regards climate, every part of the state is well adapted to the culture of Indian corn; but wheat can be grown to advantage only in the more northern parts. Indeed, even in those parts best adapted to wheat, this useful grain, except for our own immediate supply, is not found to be a very profitable crop. The new states to the north and west, in the cheapness of their lands and better adaptation to wheat from climate and soil, will always have great advantages over our state in supplying the New Orleans market. The culture of that article to any considerable extent, in Kentucky, will, in the general, be found not to be useful or advantageous, and ought, except to the extent of supplying our own wants, to be left to such of our farmers as occupy a soil not adapted to hemp and tobacco. Besides the uncertainty of the wheat crop in the rich vegetable soils of Kentucky,† it is very exhausting, and requires much

* In New England cattle are called "breachy" which break through fences.

† Liebig says, that soils particularly rich in humus are not favorable to the growth of wheat.—*Organic Chemistry*, p. 197-8.

attention to manuring and grassing of land to prevent its deterioration.

Barley is better adapted to our soil and climate, is not so exhausting, and may, in those parts of the state where there is a demand for it, be cultivated to more advantage than wheat.

In the rich vegetable soils of Kentucky, which are well adapted to the growth of hemp and tobacco, these crops, together with the necessary grains for feeding stock, such as corn, rye and oats, and the appropriate vegetables for the same purpose, should be the principal objects of culture.

Tobacco can be grown to advantage in every part of the state where the soil is suitable, but it is more peculiarly adapted to the Green River country, where the climate is better suited to the production of a first rate article.

A system of agriculture best suited to our circumstances, whilst it should embrace every variety of product, to which our soil and climate is adapted, should be so diversified as to appropriate lands of various qualities and lying in various latitudes, to the production of those articles which are best adapted to the nature of the soil and most suitable to the surrounding circumstances.

Thus lands lying near a large town or city, where the facilities for obtaining manure are very great, may be advantageously applied to the production of such articles as will serve for the consumption of the place.

By directing our efforts to the production of as great a variety of articles as the nature of our soil and climate and other circumstances will justify, we shall obtain all the advantages resulting from a division of labor, and at the same time guard against the consequences of *over production.*

If the whole energies of our state were directed to the culture of tobacco, there would not only be a misapplication of labor in attempting to produce that article in lands unsuited to the crop, but there would be an *over production,* and consequently a considerable diminution of price. If a like effort should be made to extend the culture of hemp, a similar consequence would result; and so in relation to any other agricultural product. Still greater evils would result if we were to direct all our efforts to the raising of live stock. The consequence would not only be the usual result of *a supply exceeding the demand,* but there would be a *surplus* left on hand, which would have to be fed and sustained in the hope of a *future demand* at some distant but uncertain period.

But although our agricultural efforts should be directed to as great a variety of products as circumstances will admit of, yet the *same individual* ought not to attempt the culture of too great a number of articles. In general farmers will succeed better by directing their *main efforts* to some one crop as an article for sale, and such others as are necessary to feed their stock and furnish subsistence for their families.

In one particular our system of agriculture should be uniform. Whatever may be the nature of the crops we cultivate, the utmost care should be taken so to cultivate our lands as never to suffer them to become less fertile.

Although there has been considerable improvement in our system of agriculture within the last twenty years, yet there can be no doubt we are still far behind the improvements of the age in the highly useful science of agriculture.

The extreme natural fertility of our best lands induced our early settlers to fall into the error, that it would be impossible to exhaust them. The great depth of the vegetable mould and a most excellent subsoil founded upon limestone rock, very naturally induced the opinion that it was inexhaustible. Experience has shown the fallacy of this idea, but is difficult even at this day, to make the generality of farmers sensible of the extent of deterioration which much of our naturally rich soil has already undergone; and still more difficult to convince them of the great advantages which would result from such a change of our system of husbandry as will restore our exhausted soil to its original state of fertility.

A *continued* cause of deterioration must ultimately terminate in such a reduction of soil as will render the product of less value than the labor necessary to bring it to maturity. Such a course of cultivation not only diminishes the profit of the farmer each succeeding year, until his profit is reduced to nothing, but his capital vested in land will be almost entirely sunk.

The least reflection will satisfy any one of the disadvantage of such a system. It costs no more labor to cultivate an acre of ground producing sixty bushels of corn than would be required to cultivate the same acre after it has been so reduced in fertility as to produce only thirty bushels. Now if the agriculturist who raises thirty bushels of corn per acre is barely paid for the labor expended in raising it, it is evident that the additional thirty bushels which it would have produced if the soil had not been suffered to diminish in fertility, would have been clear gain.

The same would be equally true of hemp, tobacco, and every other crop, except the small additional labor of harvesting the increased crop and preparing it for market after it has been brought to maturity.

As land can be much more easily *kept* in good heart and fertile condition than it can be *restored* after it has been deteriorated, a discreet farmer will always resort to the *easier* method, especially as it is by far the *most profitable one.*

If we take from land all or nearly all that it produces, and restore nothing, we gradually abstract from it those nourishing principles, which are essential to the growth of plants; and when the work of destruction has been carried to a certain extent, there will no longer remain in the soil a sufficient quantity of nourishing ingredients to produce a crop sufficient to pay for its cultivation. If a beneficent Providence had not made provision for a supply to a considerable extent of those elementary principles which constitute in various states of combination, the appropriate food of plants over and above what is furnished by the soil, our best lands under a bad state of cultivation would long since have been reduced to a state of complete sterility. In a state of nature every thing is restored to the soil which is drawn from it by the growth of plants, and hence it continually increases in fertility. To preserve the fertility of land while in a state of *cultivation,* it is only necessary to restore to the soil such a proportion of the fertilizing ingredients as will, together with those furnished from the atmosphere, be equivalent to the sum of those drawn from the soil by the growing crops.

The office of the soil is, "1. To receive and digest the food designed for the growing plant. 2. To serve as a medium for conveying to the spongiolets or mouths of the plants the water holding in solution the different substances which pass into and nourish them; and, 3. To serve as a basis for fixing the roots of the plants, and maintaining them in an upright position." *

The following are the most important elementary principles, which, in various states of combination enter into the composition of vegetable matter, and furnish the appropriate food for growing plants; oxygen, hydrogen, nitrogen and carbon, together with a small portion of the alkalies and oxides of various metals. So far as these elementary principles are supplied from other sources than the soil in which crops are grown, the waste occasioned by their removal is replenished. Plants possess the power of decomposing water,† and appropriating its elements by assimilation as food; and as water is composed of hydrogen and oxygen, it follows that two of the foregoing elements are derived in large quantities from the atmosphere through the medium of rain, snow and dews.

Liebig, in various parts of his able work on organic chemistry, has shown that plants derive from the atmosphere, by the absorbing power of their leaves, a large and regular supply of carbon in the form of carbonic acid. He adds that during the heat of summer, (a plant) derives its carbon exclusively from the atmosphere."‡

Here then we have the source whence is derived in large quantities three of the principal elements, which in various states of combination assist in furnishing food for growing crops. Nitrogen is known to be essential to the healthy and vigorous growth of plants. This element exists in large quantities in all animal substances, and also to a considerable extent in decaying vegetable matters, but much of it escapes in the form of ammonia during the process of decomposition. It was difficult until recently to account for the manner in which the loss (sustained by soils while in cultivation) of this indispensable ingredient of fertility, is replenished. Liebig has shown in a very satisfactory manner that ammonia (composed of three parts, by weight, of hydrogen, and 14 parts nitrogen) is combined with rain water and snow in small quantities, and hence the loss of nitrogen sustained by the removal of crops from the soil on which they grew is, in a limited degree, restored by the falling of rain and snow. Thus nitrogen, to some extent, is also supplied by the atmosphere to growing plants; but as this supply is not so abundant as that of the other elements, the utmost care should be used by the cultivators of the soil to keep their lands well supplied with this indispensable ingredient of fertility, by taking nothing from the land but what is necessary, by restoring in the form of manure every thing that can be restored, and by cultivating clover and other ameliorating crops which take but little from the soil, while they add to it all the fertilizing ingredients which they derive from the atmosphere. When these circumstances are duly considered we may readily account for the length of time during which a soil may be cultivated in the worst possible manner, without entirely exhausting it. A continued effort is made by nature to replenish the earth with those fertilizing ingredients which have been inconsiderately wasted by the improvidence of man, without any effectual effort on his part to restore even the small proportion of those ingredients which would furnish a full supply of food for future crops.

When a beneficent Providence has done so much towards restoring the elementary principles constituting the food of plants, which, to a certain extent, must be consumed by the growing crops, a strong encouragement is held out to the industrious farmer to do his part also. In looking around he beholds every where the evidence that when all is restored to the earth which grew upon it, a continued increase of fertility results. This is a sure indication that a beneficent Providence intended that the earth should never become sterile by cultivation—it plainly points out to man that he too should restore to the soil that portion of its products for which he has no use. He should continually bear in mind that the aids, provided by a bountiful Creator, were only intended to supply the *unavoidable loss* of nourishing ingredients or food for plants, occasioned by the necessity of taking from the soil a portion of the growing crops for consumption, and which cannot, therefore, be fully restored. While, therefore, the prudent farmer may confidently rely upon these aids in preserving the fertility of his soil, he will recollect that he must also do his part. He may take for consumption the fruits of the earth for both man and beast, and yet give back to it enough to keep up its original fertility, by restoring only a reasonable proportion of that part of its product which remains after consuming all that is of any value for food for himself and provender for his stock.

Next to oxygen, hydrogen, carbon and nitrogen, the alkalies, potash and soda, constitute the most important ingredients, in the food of plants. These were formerly considered as simple substances, but were ascertained, by Sir Humphry Davy, to be metallic bases, combined with oxygen. They are therefore real oxides. They are capable of combining with a great variety of substances; and, in various states of combination, form an indispensable food for plants of almost every kind. Hence if these substances were entirely extracted from the earth, it could no longer produce a vigorous growth of those plants which require a supply of these alkalies as a part of their food.

Liebig has shown, that these alkalies exist in a state of combination with water, in small proportions, and that where they have been extracted from the soil by growing plants, they may be restored by irrigation, and by rain.* Sea water also contains these alkalies in small quantities, and Liebig informs us that "the roots of plants are constantly engaged in collecting from the rain those alkalies, which formed part of the sea-water, and also those of the water of springs, which penetrates the soil." That, "without alkalies and alkaline bases most plants could not exist."†

The alkaline earths, lime and magnesia, are

* Farmers' Companion, p. 50.

† Liebig's Organic Chemistry, 122.

‡ Liebig's Organic Chemistry, p. 106 See also p. 54 and 55.

* Liebig's Organic Chemistry, 159, 160.

† See further on this subject, p. 196 to 200.

necessary to the vigorous growth of some of the most valuable agricultural products. These earths exist in great abundance, in some soils, but in others are very deficient, particularly in lime. This deficiency is, in some degree, supplied from the atmosphere. Liebig informs us that " by the continual evaporation of the sea, its salts are spread over the whole face of the earth ; and being subsequently carried down by the rain, furnish to the vegetation those salts necessary to its existence. This is the origin of the salts found in the ashes of plants, *in those cases* where the soil could not have yielded them."* Besides a small quantity of *sulphate* of lime, there is contained in sea-water, according to Liebig, 1.12400 of its weight of *carbonate* of lime.

Thus it is seen we are indebted to the atmosphere not only for oxygen, hydrogen, carbon, and nitrogen, but also for potash, soda, and the alkaline earths—lime and magnesia. The importance of these will be further noticed, when I come to remark upon manures.

The means of preserving the fertility of the soil, and renovating that which has been partially exhaused are,

1. A judicious rotation of crops.
2. The saving and applying of manures.
3. A liberal cultivation of such crops as receive their chief nourishment from the atmosphere.
4. Good tillage.

As a distinct premium has been offered for the best essay on the rotation of crops best suited to Kentucky, I do not propose, in this essay, to say any thing on that branch of the subject.

The saving and applying of manures is very important to a good system of husbandry. And great care should be taken to preserve so much of the product of the farm, as is left unconsumed by man and beast in suitable situations, to be used at the proper time, for that purpose.

The necessity for suitable application of manure, to cultivated lands, is very evident when we reflect, that some of the most important ingredients which serve as food for plants, such as nitrogen, potash and soda, are furnished but sparingly from the atmosphere. These ingredients are all found in manures ; and by properly saving and applying them, the farmer is enabled to make up the deficiency of the supply from the atmosphere. Manures contain also other useful ingredients, which, perhaps, can be derived from no other source.

A question of great importance, and one which seems not yet to be fully settled, is what is the best manner of preserving manure till the proper period of applying it to the land in cultivation, and in what condition should it be applied, whether after complete decomposition has taken place, or when only partially decomposed or in the state in which it came from the earth ? Liebig, in his able work on organic chemistry, in its application to agriculture and physiology, has shown that ammonia is a very important ingredient, in the nourishment of all agricultural products.

During the decomposition of manures, a large quantity of ammonia is formed, but being a gaseous substance the whole passes off, and is entirely lost. If, therefore, long manure is exposed in heaps to the effects of heat and moisture, fermentation ensues, and the consequent formation of ammonia, which passes off in the form of gas, and nothing is left, as he informs us, but "a mere carbonaceous residue of decayed plants." An idea of the loss sutained by manure, exposed to heat and moisture, may be proved by the fact stated by Liebig, "that with every pound of ammonia which evaporates, a loss of sixty pounds of corn (wheat) is sustained." To prevent this loss Liebig recommends "that the floors of our stables, from time to time, be strewed with common gypsum, (sulphate of lime,) the ammonia (he says) enters into combination with the sulphuric acid, and the carbonic acid with the lime, forming compounds which are not volatile, and consequently destitute of smell.*

Growing plants receive large supplies of oxygen and hydrogen (the component parts of water) from rains and dews. They are also supplied abundantly with carbon, in the form of carbonic acid, by means of the absorbing power of their leaves. But a full supply of nitrogen and the alkalies is likewise essential to their vigorous growth. These are more sparingly supplied from the atmosphere, and hence the importance of additional supplies. Putrescent manures abound in nitrogen, but this important element of vegetable food, during the process of putrefaction, nearly all escapes (if no measures are taken to fix it) in the form of ammonia.

Liebig has shown, that this may be done by a proper application of gypsum to stable manure before the fermentating process commences.† A similar application of gypsum to manure, saved in feeding pens, cow yards, &c., would, no doubt, have a most beneficial effect, but it must be remembered, that ammonia is readily absorbed by water, and consequently large portions of it may be lost, where the manure is so exposed as to become satured with that fluid. Every precaution, consistently with a due regard to economy, should be used to prevent this. Placing the manure under sheds, and intermingling with it a due proportion of gypsum, would be the most effectual way to guard againt the loss of ammonia. But in general this would be attended with too much expense. The next best method is to so place the manure, preparatory to its undergoing fermentation, as not to subject it to the drainage of the adjacent grounds, or the dripping of water from the roofs of stables, cow sheds, &c. The former object can be attained by a judicious selection of suitable ground for feeding yards, and by cutting ditches where necessary, to carry off the water. The latter may be secured by erecting stables, sheds, &c., so as to have the manure thrown out at the gable end, where there can be no dripping from the roof. Where stables or sheds have been already erected upon a different plan, the drippings from the roof may be carried off by leading troughs. These precautions would leave the manure subject only to the effects of rain falling immediately upon it. To guard against this, the manure should be kept in com-

* Liebig's Organic Chemistry, 166.

According to Marcet, sea-water contains in 1000 parts :

26.660 chloride of sodium. 4.660 sulphate of soda. 1.232 chloride of potassium. 5.152 chloride of magnesium. 1.5 sulphate of lime.

* Liebig's Organic Chemistry, 239. † Ib. 239.

pact heaps, so as to expose as little surface as possible to the falling rain; to this end the manure collected in cow yards, feeding pens, &c., should occasionally be thrown into heaps in the form of a stack, mingling therewith, during the process, a due proportion of gypsum. A still further precaution might be used, by removing the manure, as soon as it is in a fit condition, to the fields for which it is destined, and there spread. This would check any remaining disposition to ferment, and the falling rains would carry the ammonia down into the soil, with which it would combine, and thus all danger of further loss, to any considerable extent, would be avoided. From what has been said, it will be seen that manure is liable to great loss during the process of fermentation, unless the utmost care is used to prevent the escape of ammonia. If manure is suffered to undergo complete decomposition, there will be a considerable saving of labor in hauling and spreading, and much less difficulty in ploughing the ground on which it is distributed, but there will be more or less loss of some of the most valuable ingredients of the manure. If the proper precautions are used to prevent the escape of ammonia, perhaps upon the whole, it will be found most advantageous to suffer the manure to undergo at least a partial decomposition, before it is removed to the fields for which it is intended. But, notwithstanding every precaution that can be used in preserving and applying putrescent manures, some loss will be sustained. Ammonia readily enters into combination with carbonic acid, forming a volatile compound, and is itself, while in a gaseous form, with all its volatile compounds, extremely soluble in water.* And hence every particle of water evaporating from a dung heap will carry with it ammonia and carbonic acid, unless they shall have been converted into a salt, which is not volatile. Alumina (clay) exercises an indirect influence on vegetation, by its power of attracting and retaining water and ammonia."† Liebig informs us, that "a part only of the carbonate of ammonia which is conveyed by rain to the soil is received by plants, because a certain part of it is volatilized with the vapor of water." But if the soil contains a due proportion of gypsum, or when deficient in this respect, if it should be supplied from time to time with gypsum, "the carbonate of ammonia, contained in rain water," (and of course that which is carried down into the soil by rains, falling on putrescent manures) "is decomposed by gypsum, in precisely the same manner as in the manufacture of sal-ammoniac. Soluble sulphate of ammonia and carbonate of lime are formed; and this salt of ammonia, possessing no volatility, is consequently retained in the soil. All the gypsum gradually disappears, but its action upon the carbonate of ammonia continues as long as a trace of it exists."‡ It will be observed from the reasoning of Liebig, that the ammonia which the soil receives during the decomposition of long manure, which may be left or spread on the ground, is also liable to sustain a loss by combining with water and passing off in the form of vapor. But as in this case, the process of fermentation is very slow, the carbonate of ammonia will have more time to combine with the soil, and the roots of plants are constantly engaged in absorbing it. During slow fermentation there is probably but little loss of carbonate of ammonia, even when gypsum is not present, and when present none at all.

So far, therefore, as the products of the soil, which are not useful for the consumption of man or beast, can be left on the ground, that will be the most economical application of manure. In this mode of applying it, the labor of transporting and distributing it will be saved, and much less loss will be sustained by evaporation than where the decomposition is rapid, and no gypsum used. Thus it will be advantageous to leave upon the ground as much of the stubble of wheat, rye, &c., as can be left consistently with an economical saving of the grain. With the same view corn stalks may be left on the ground and ploughed in. The straw of rye and oats, fed off to stock, and of the second crop of clover when fully ripe, will also be of great advantage to the soil. All these will undergo slow fermentation, and if not suffered to be washed away by heavy rains from rolling lands, will add much carbonate of ammonia and some potash to the soil. Liebig informs us, that "ammonia, evolved from manure, is imbibed by the soil, either in solution in water, or in the gaseous form, and plants thus receive a *larger supply of nitrogen* than is afforded them by the atmosphere."* Indian corn, as well as rye and oats, is sometimes fed off by turning stock in the field. In this mode of feeding the whole product of the soil is restored, and the land must necessarily be enriched, in proportion to the quantity of nourishing ingredients, which the growing crop received from the atmosphere, (always a large proportion,) with such abatement only as will be equal to the loss of ammonia, sustained by evaporation.

In the remarks I have hitherto made on manures, I have not referred to one species, which Liebig considers of very great value, I allude to human excrements. This subject is treated very much at large, in the work to which I have so often referred, but it would extend this essay to too great a length to go fully into an examination of this very important ingredient. A few extracts will be sufficient to show its importance. At p. 242 he remarks, "that if we admit that the liquid and solid excrements of man, amount on an average to 1½ lbs. daily, (5·4 lb. urine and ¼ lb. fæces,) and that both taken together contain 3 per cent. of nitrogen, then in one year they will amount to 547 lbs. which contain 16.41 lbs. of nitrogen, a quantity sufficient to yield the nitrogen of 800 lbs. of wheat, rye, oats, or of 900 lbs. of barley."

"This (he observes) is much more than is necessary to add to an acre of land, in order to obtain with the assistance of nitrogen absorbed from the atmosphere, the richest possible crop every year. Every town and farm might thus supply itself with the manure, which besides containing the most nitrogen, contains also the most *phosphates*; and if an alternation of crops were adopted, they would be most abundant. By using at the same time, bones and the lixiviated ashes of wood, the excrements of animals might

* Liebig's Organic Chemistry, p. 130. † Ib. 191. ‡ Ib. 141, 142.

* Liebig's Organic Chemistry, 141.

be completely dispensed with." At page 246 he says "that with every pound of urine a pound of wheat might be produced."

At page 241-2 he states that liquid animal excrements, such as the urine with which the solid excrements are impregnated, contain the greatest part of their ammonia in the state of salts, in a form, therefore, in which it has completely lost its volatility; when presented in this condition, not the smallest portion of ammonia is lost to plants, it is all dissolved by water and imbibed by their roots."

I will quote but one more passage which goes to show the great superiority of human manure over that of other animals. "In respect to the quantity of nitrogen contained in excrements, 100 parts of the urine of a healthy man are equal to 1300 parts of the fresh dung of a horse, according to the analysis of *Macaire* and *Marcet*, and to 600 parts of those of a cow."

Ashes of wood and vegetable substances from which potash is derived, is also a very important manure. "Most plants, perhaps all of them contain organic acids of very different composition and properties, all of which are in combination with bases, such as potash, soda, lime or magnesia."* Without alkaline bases, Liebig says, "most plants could not exist." And it is a remarkable fact that where there is a want of the usual alkaline base in a soil, suitable to a particular plant, another alkaline base will be substituted.† This fact shows the indispensable necessity of an alkaline base in all plants. If further proof were wanting the fact that all trees and plants contain more or less of the alkaline bases would be perfectly satisfactory. Some trees require much less alkali than others. Thus pines and fir trees require a much smaller quantity of the alkaline bases than other species. And consequently the former thrive well on a soil where the latter could not exist.‡ One hundred parts of wheat straw yield 15.5 parts of ashes; the same quantity of the dry stalks of barley 8.54 parts; and of oats straw only 4.42. The ashes of all these are of the same composition."§ The facts here stated, prove that wheat is much more exhausting of this particular manure than barley or oats.

Of such great value are ashes esteemed in Germany, that they are transported, as Liebig informs us, "from the distance of 18 or 24 miles." They are particularly valuable to meadows, as these are constantly drained of their potash by the annual removal of the crops of hay—a crop containing a large portion of that ingredient.

It is obvious that if a soil contain only a limited quantity of potash, it must in time be entirely exhausted, if the growing crops are annually removed, and no part of the product is restored, unless a supply is derived from some other source.

The atmosphere furnishes a small quantity, but by no means sufficient to replenish the waste occasioned by the growing crops, and hence the necessity of making up the deficiency by the application of ashes and other manures, containing potash.

Liebig relates an extraordinary instance of the effects of depriving a soil of its potash, which occurred in the vicinity of Göttingen. A proprietor of land, "in order to obtain potash, planted his whole land with wormwood, the ashes of which are well known to contain a large portion of the carbonate of that alkali. The consequence was that he rendered his land quite incapable of bearing grain for many years, in consequence of having entirely deprived the soil of its potash."*

Liebig says, "it is the greatest possible mistake to suppose that the temporary diminution of fertility in soil is owing to the loss of humus; it is the mere consequence of the exhaustion of the alkalies."† He states a variety of facts to corroborate this opinion. When we reflect that the principal ingredient, furnished by humus to the growing plants, is carbon in the form of carbonic acid, and that plants derive a very abundant supply of this element, *after* the formation of their leaves from the atmosphere, by means of their absorbing power, we cannot but regard the opinion that the diminution of fertility in soils is more owing to the loss of alkalies than humus, as at least very plausible. Liebig is of opinion that the great diminution in the fertility of the soil in Virginia, since its first settlement, is owing to the exhaustion of its alkalies. He estimates that "from every acre of this land, there were removed in the space of one hundred years 1200 lbs. of alkalies in leaves, grain and straw; it became unfruitful therefore because it was deprived of every particle of alkali which had been reduced to a soluble state; and because that which was rendered soluble again in the space of one year, was not sufficient to satisfy the demands of the plants."†

Silicate of potash is an ingredient of indispensable necessity to the vigorous growth of the small grains, and of all plants of the grass kind. Ashes is the source whence it is derived, and hence the importance of saving and applying this manure to our cultivated land, and particularly to that which is appropriated to meadows and raising of wheat. Ashes which have not been lixiviated are of the greatest value, as a manure, but after having undergone that process, they still contain silicate of potash, and salts of phosphoric acid, and consequently are of great importance as a succor to all plants of the grass kind.‡

Phosphoric acid is also a very important ingredient, particularly for the small grains. It is found in the ashes of all plants, "and always in combination with alkalies and alkaline earths." "The seeds of corn (wheat) could not be formed without the phosphate of magnesia, which is one of their invariable constituents."§

I cannot quit this subject without recommending to every agriculturist, a diligent study of Liebig's very able work an agricultural chemistry, and particularly that part of it which treats of manures, and the means of preserving the fertility of soils.

Although the manuring of lands, if proper care be taken in collecting, preserving and distributing them, will do much towards preserving their fertility, and renovating such as have been deteriorated by bad husbandry, yet other means can be resorted to, with great advantage in has-

* Liebig's Organic Chemistry, 148. † Ib. 149. ‡ Ib. 198. § Ib. 199.

* Liebig's Organic Chemistry, 161. † Ib. 196. ‡ Ib. 228. § Ib. 200, 201.

tening the process. A judicious system of grassing our lands which can be accomplished with but little labor, will always be found very useful, and must enter largely into our system of agriculture.

Red clover, there can be no doubt, is the best adapted to this purpose. In consequence of its thick growth, and its numerous and broad leaves, it is well suited to draw nourishment from the atmosphere; and does so, perhaps, in a greater degree than any other grass, except other species of the trifolium. Red clover is one of the tribe of leguminous plants, which "are remarkable on account of the small quantity of alkalies or salts in general, which they contain."* The *medicago sativa* (lucerne) according to Liebig contains less than one per cent. (0.83) and red clover probably does not contain more. Hence one great advantage in the cultivation of this crop will be that it requires to sustain its growth but a very small portion of alkali, while it will absorb from the atmosphere not only that ingredient, but also nitrogen in the form of ammonia, and will thus add to the soil two very important ingredients that enter into the constituents of the food of plants. When we take into consideration, that nitrogen and the alkalies are indispensably necessary to the growth of plants, and that these substances are very sparingly supplied from the atmosphere, we will perceive the great importance of the clover crop in restoring and preserving the fertility of soils. Besides, this crop will furnish fine pasturage in the early part of the year, when other grasses are too short for that purpose. After being fed off by stock, whose manure is left on the ground, it produces a luxuriant second crop, which may either be fed off in the fall, or left as a coat of manure upon the ground. This may be repeated two or three years in succession, as circumstances may require. The last crop, when fully ripe, should be ploughed under in the fall of the year, and will thus furnish a coat of manure for the succeeding crop. If ploughed under when green, the operation will necessarily have to take place during warm weather, and consequently a rapid decomposition and escape of ammonia would ensue. This should always be avoided.

Blue grass is also valuable in restoring the fertility of land, but the process is more slow, and should only be resorted to in lands intended for cultivation, where they can be conveniently left in grass some eight or ten years.

Rye is a crop that exhausts but moderately when the grain is reaped; and when fed off by stock upon the ground on which it grew, is a rapid restorer of soil which has not been much exhausted. It is attended with the advantage of producing two crops from a single sowing, the second always springing from the seed left on the ground by the grazing stock.

The liberal cultivation of grasses and rye—to be fed off by stock—coupled with a judicious rotation of crops, will undoubtedly have a powerful effect in restoring the partially exhausted lands of Kentucky, but a judicious system of manuring, as recommended in this essay, would greatly add to the rapidity of the process, and should by no means be neglected, especially when lands have been considerably deteriorated by bad husbandry.

Little need be said to show the necessity of good tillage in any tolerable system of agriculture. If land be carelessly cultivated, weeds not only draw from the growing crops a portion of the nourishment, which ought to have gone to their sustenance, but they also tend to diminish its fertility. Besides, air is essentially necessary to the growth of plants, so much so that Liebig informs us that "without oxygen, neither seeds nor roots can be developed." If the soil be kept light, and finely pulverized, it greatly increases its capacity for absorbing air and moisture. And as "plants during their life constantly possess the power of absorbing by their roots, moisture, and along with it, air and carbonic acid,"* it follows, that "by loosening the soil which surrounds young plants, we favor the access of air, and the formation of carbonic acid; and on the other hand, the quantity of their food is diminished by every difficulty which opposes the renewal of air."†

Thus, by a careful and diligent cultivation of land, the crop is furnished more abundantly with its appropriate food, is kept free from the contaminating influence of weeds, is furnished with a due quantity of air, and is not obstructed in its growth by the baked earth with which careless cultivation leaves it hampered. And in addition to the advantages resulting to land, the diligent husbandman is rewarded with a greatly increased crop, and the prospect of being relieved from much labor in future, by exterminating all noxious weeds from his arable grounds.

Liebig affirms that "the agriculture of China is the most perfect in the world," and *there no weeds are suffered to grow.*

If, by any, it should be thought I have been too minute in describing the elementary principles constituting the food of plants, I rest my justification in the opinion expressed by Liebig, that "any great improvement in that most important of all arts (agriculture) is inconceivable without a deeper and more perfect acquaintance with the substances which nourish plants, and with the sources, whence they are derived."‡

The judgment of Liebig will doubtless be a sufficient apology, unless we are content to be still subject to the reproach that "agriculture has hitherto never sought aid from chemical principles, based on the knowledge of those substances which plants extract from the soil on which they grow, and of those restored to the soil by means of manure."§

BERKSHIRE HOGS.

From the Farmers' Cabinet.

An article in the last Cabinet, under the caption of Berkshires, and containing so very unfair a judgment on the merits of that invaluable breed, over the signature of R. S. B., Northampton county, together with the severe strictures of G. H. D., where the Berkshire mania, so called, is classed with the humbugs of the day, seem to make it proper for their friends, if they have any

* Liebig's Organic Chemistry, 83. † Ib. 106. ‡ Ib. 62. § Ib. 207-8.

left, to protest against their being thus unceremoniously killed off without benefit of clergy. Indeed, at this time, when, with the versatility peculiar to American character, the agricultural press is teeming with anti-Berkshire essays, condemning, in louder tones than ever were uttered in its favor, the whole breed, as a Merino sheep, multicaulis humbug, it might seem almost presumptuous, even in one who has tried them, to endeavor to stem the torrent. It seems unfortunate that, on the introduction of any thing new, either in agriculture, science, or the arts, in the thermometer of public opinion, the mercury, starting at zero, must rush up immediately and rapidly throughout its whole range, and all the way back to the starting point, and even below it before it finally attains its proper state of quiescence. Particularly on the introduction of a new breed of animals, we seize on them with great avidity from the mere novelty, invest them with extravagant and supernatural qualities, proclaim the wonderful things they *are to do*, and when at last they fall short of these calculations, the whole affair is pronounced a "Merino, multicaulis humbug." From being placed in the first instance far above their merits, they are next placed far below them. This, in the United States, is always the modus operandi of introducing new breeds of stock to farmers, who, after passing through the high fever stage of heavy profits, and down again to the cold or collapse, at last finally settle in a medium temperature, and give to the new breed whatever is its just value. To this process Berkshires must submit. R. S. B., in the communication referred to, does not make the true issue. He says one of his neighbors put up two Berkshires and two common hogs in a *stable* to feed, and that the common ones outweighed the others. This is very probable, but does not prove the main point, *that the Berkshires did not return the greatest weight for the quantity of food consumed.* Berkshire breeders do not contend that *generally* they attain such great weights as other hogs, but that a given amount of food will make a greater quantity of pork; that if it does not feed such large hogs, it will feed a greater number. I have so fully satisfied myself of this point, that, although owning some very fine ones of the Chester county breed, I have killed them off, and intend keeping nothing but the thorough-bred Berkshire. At about 12 months old they will weigh from 200 to 260 lbs., being ready for slaughter at any period of their growth, and requiring at last but a few days' feeding upon corn to harden the meat. The shape of the true Berkshire is perfect, forming the beau ideal of a perfect animal; the bone fine, the head and all the offal parts very small, the most valuable parts, the hams and shoulders, full, round and large. Occasionally it is admitted that they have not sufficient depth, but this is only an exception. Where it occurs, the owner must remedy it by careful selection. This cannot be made a valid objection, for there is no breed, however pure and perfect, of any animals, but that something must depend on the judgment and talent of the breeder to keep so, and to remedy any occasional or inherent defect. Something approaching the barrel form must of necessity accompany the quality of easy feeding. In regard to size, the farmers here who feed a few every fall for Philadelphia market, besides what is wanted for home consumption, find that a hog weighing from 150 to 250 lbs. is the most saleable and brings the best price. The Berkshires make just the weight wanted for family use. Whether in Northampton county, where grain is lower than here, they cannot *afford* to waste it on large consumers, which will carry to market greater weight and size, is for him to say. Another characteristic of the Berkshire is the superior quality of the meat. In this at least there is no mistake. Berkshire hams are well known in Philadelphia for their superior flavor and richness. They are remarkably free from fat, and are no less known by their handsome rotund shape, than by their tender and juicy qualities. A slice of Berkshire ham, properly cured, is a dainty morsel appreciated by a connoisseur. Another recommendation is the great fecundity of the breed, producing from 8 to 15 at a litter, and the fact of their being most excellent nurses. By a most unaccountable mistake, R. S. B. objects to them on this very head, and says they are not prolific, that four of his neighbor's sows had but one each, and that generally they have but four or five. I have raised Berkshires for several years, have sold numbers of them, not only in this neighborhood, but to gentlemen at a distance, and as far as my experience and observation go, would say they are not more noted for their *black* color than for their success in safely rearing a full average number.

The true question then at issue, at least in this section of country, is, *what breed of hogs will return the greatest weight for the quantity of food consumed.* Here lies the profit more than in the individual weight. A small, well-made animal may bring more money to the farmer, than one of twice his size, from the difference in the fattening property. It is generally admitted that very large animals are not profitable. They may do to grace the columns of a paper, and gratify those who have a penchant that way, without regard to the expensive process, but they will not suit the common farmer. I once was seized with this desire to feed a large hog; I purchased of a breed well known for attaining immense weights, but was completely cured. It weighed between five and six hundred, and consumed as much food as I am since satisfied would have fattened double the weight of Berkshires. It is a satisfaction to the early friends of the Berkshires, to observe that public opinion in respect to them has passed through the collapse state; that wherever the pure breed exists, prejudices even against color are rapidly dying away; and that they are slowly but surely creeping into favor, and earning the emphatic appellation of the farmer's hog. One thing undoubtedly which has retarded and still retards their reputation is the vast number which, since they were first introduced, have been palmed off as genuine Berkshires, having very little if any of that blood. The cause of this is to be found in the high prices at which they were sold, $30 and $40 per pair, and the absurd rule for testing purity, that they must be precisely of a certain shade of color, having so many white feet, and so many white hairs in the tail; thus inviting imposture, and inducing persons, wherever they could obtain these marks, which often appertain to a half or three-quarter blood, as well as to the full blood, to pass them for genuine Berkshires. A cross

for the purposes of specu'ation has, no doubt often been founded on very inferior stock. The true Berkshires have thus been made to bear not only their own burdens, but have been charged with the sins of a whole herd of worthless mongrels. However breeds may be denoted by certain external marks, either of color or shape, no rule for all cases can be invariably established: there will occasionally be exceptions. Durham cows generally run into light colors, and it is more absurd to say that Berkshire pigs are or are not pure on account of their feet or tail, than to condemn a Durham cow which happened to be of a red color, or had a dark nose. P. M.

East Bradford, Chester Co., Pa.

MURRAIN IN CATTLE.

From the Farmers' Cabinet.

We have sad accounts from England respecting the fatal disease which is carrying off their cattle by hundreds, and think that Mr. A. B. Allen did wisely in abstaining for the present from bringing over any horned cattle. It is said the veterinary surgeons term the disease the bloody murrain, and consider it infectious: now I know not how this can be, for amongst the very many cases that I have witnessed, I have never been able to convince myself of that fact. It is true that to a casual observer it may have the appearance of being so, for the cattle in a large pasture, or even in a whole parish or hundred, will oftentimes be attacked by it, and the disorder will spread abroad like a contagious fever, but I have no doubt the evil arises from a disordered state of the digestive organs, brought on by an unwholesome state of the atmosphere, or by feeding on unhealthy pastures, those low, cold and damp meadows, infested by aquatic plants, which, being taken into the stomach, become putrid and indigestible; and thus that noisome and putrid disease is engendered. For I have known one half the cattle upon a certain farm to be carried off by it, while not a single case has occurred on the immediately adjoining estate, but on the next farm again to that, the whole herd has been swept away; and just so have I observed the produce of their pasture lands to vary from dry, sweet and healthy herbage, to that which is long, moist, sour and unwholesome. And I am inclined to believe that the murrain in cattle, like the botts in horses, may be considered an *effect*, rather than a *cause*, both disorders arising, perhaps, from an unhealthy state of digestion, by which is engendered a disease, which, although it must be termed epidemic, might not be by any means infectious; indeed I well remember a dairy of fine cows which was thinned to less than one-half its original number, where the individuals were attacked by the disease on being confined to their winter quarters, the occupants of stalls 1, 3, 4, 6, 8, 10, &c., being carried off, while the intermediate numbers escaped uninjured, and remained in perfect health.

But to many persons it will no doubt seem strange to consider the origin of two disorders, so very different in their appearance, symptoms and effects, as the botts and murrain, as arising from the same cause, namely, indigestion, but as I conceive that they are engendered by a disordered state of the stomach caused by sour and unwholesome food, and that they might both be cured, or which is better, be *prevented*, by timely administration of a medicine, 'alkaline in its nature, I believe that reason will bear me out in the conclusion to which I am partly led by perusing an article on this subject in the Cabinet, vol. 4, p. 177, where it is said—quoting from the American Farmer—"Some years since I purchased a horse, but he had the appearance of laboring under disease; I commenced a course of treatment which I had before pursued in cases similar to appearance, but without effect; I was therefore induced to try the use of *lime*, as I was confident he was filled with botts, for he had discharged several; I therefore commenced by giving him a table-spoonful of slacked lime three times a week in bran mashes. After pursuing this course near two weeks, the botts began to pass away in quantities, varying from ten to twenty, which he would expel from his intestines during the night; in the mean time his appetite began to improve, and in six weeks he was one of the finest geldings I ever saw; from that day to this I have kept up the use of lime amongst my horses with decided benefit; and as an evidence of its good effects, I have not lost a horse since I began to use it. And lime is a certain preventive in keeping cattle from taking the murrain. As an evidence of this fact, I have used it among my cattle three times a week, mixed with salt, for three or four years, and in that time I have not lost a single animal by this disease; but in the mean time some of my neighbors have lost nearly all the cattle they owned. But I will give a stronger case than even the one above mentioned. One of my neighbors who lost all his cattle, had a friend living within two hundred yards of him, who had several cattle which ran daily with those that died, and his cattle all escaped—he informed me that he made it an invariable rule to give his cattle salt and lime *every morning*. I have, therefore, no doubt but salt and lime are a sure and infallible remedy for botts in horses and murrain in cattle."

And I am reminded of a circumstance by a friend, who has often before mentioned it; he had two fields of pasture near his house—on one of these he spread lime upon the turf to the amount of more than 200 bushels per acre, but as the other field lay immediately below his cattle-yard, from whence he had formed drains to carry the water over its surface in the most complete manner, he determined to let that suffice for a dressing; and the effect of the highly impregnated water from the yard was a growth of grass truly astonishing. Both fields were kept in pasture, and when the stock had eaten one of them down, they were removed to the other, and so changed regularly about; but the effect of the different crops on the appearance of the stock, horses and cattle, is not to be expressed, for while feeding on the limed land their coats were close, shining and healthy, and their spirits light and cheerful, even when they were compelled to labor hard to obtain a bellyful; but when turned into the watered grass, six inches or more in height, a difference for the worse could be perceived in 24 hours, and every day after they lost condition amidst the greatest abundance, with coats rough and staring,

lax in the bowels and flaccid, with distended paunches, dejected countenances, and sluggish in their movements; they soon exhibited a depreciation in value to the amount of about half their former worth. But the transition to health and vigor and good looks was quite as sudden and apparent on a return to the limed land; for again in 24 hours, or by the time the food had passed through the system, a change, particularly in their air and carriage, was very perceptible. My friend adds, he never had an instance of the murrain or botts while his stock fed on these pastures, but is satisfied he should have had both, but for the change to the limed land; for while feeding on the watered pasture, the stock had always the appearance of a predisposition to that state of derangement of the digestive system, by which he has no doubt these diseases are engendered.

In conclusion, I would ask, is it not quite fair to draw the following deduction from what has been said, namely, that all dairy pastures ought to be heavily limed, it being the most natural thing in the world to suppose that a proper secretion of milk, the best and most wholesome, depends very much on the nature of the food with which the animals are fed? and must not the butter from a cow that is in health and spirits be of better flavor, color and consistence, than that from one that is lax, washy and weak, from feeding on watery, acid and soft herbage? and will not this account for much of the disgustingly rancid, ill-flavored and ill-looking butter which we so often find in the market? My friend above quoted, and who is now at my elbow, answers "Yes; for while my cows fed on the watered meadow, the butter was scarcely eatable—white, soft and ill-flavored, but it was sweet, firm and fine-flavored when they were confined to the limed land." Ergo, lime your pastures, and allow your stock as much salt as they will consume daily, for I am convinced that lime and salt are a remedy for "botts in horses," as well as the "murrain in cattle." VIR.

REMARKS UPON ENGLISH CATTLE, AND A COMPARISON OF THEM WITH AMERICAN.

From the Kentucky Farmer.

It has become a matter of great importance to the American stock-breeders, to know now whether they can make any further improvements in their domestic animals, and if so, how, when and where. It would require too long an essay to be read before this society, to attempt to go over the whole circle of British domestic animals. I shall, therefore, in this paper, after an incidental paragraph, confine my remarks to neat stock alone, which at present probably most interests Kentucky.

I was not only at the annual meeting of the Royal Agricultural Society, but present also at that of Yorkshire, which was much superior in its show over the former, in horses, short horns, long wool sheep, and swine. I also privately examined the stock of many of the most distinguished breeders in Great Britain, and am free to declare, that, a few South Devon sheep excepted, we want scarce any thing more from abroad for years. Our roadsters and horses of all work, are superior to those of England, in shape, action and endurance—our cattle nearly as good. With fine wool sheep she has nothing to compare with us, and our splendid herds of swine, improved by the late importations, are now made quite equal to any.

Short-horns.—Just before leaving for England last spring, I took a careful survey of Ohio and New York, and since my return have gone again over much of the same ground, together with the addition of a part of Kentucky; and this second look has only the more fully confirmed me in the judgment that I formed while abroad, that, the *best* of one breeder's herd alone excepted, the short-horns of America, are quite equal to those of Great Britain. I therefore do hope, till the choicest of these can be had at a reasonable rate, that our money may not be wasted abroad in the pride of further importations—more especially during these hard times, and under the consideration of the little that Europe is taking of our agricultural products in return. Short-horns bred here can now be purchased throughout the country, of as good a quality as abroad, for half the money that it would cost to get them from there. Let us appreciate then what we already possess, foster, cultivate and spread it—*free ourselves from the* THRALDOM of foreign opinions, and no longer be carried away by the fashion of the word—"*imported.*"

I found English breeders very slow to believe that their stock, brought over here, were made *better*, rather than *deteriorated* in the change. Such a thing they thought utterly impossible in poor ignorant America. But that a great and decided improvement has been made in it, when fallen into any thing like judicious hands, can be demonstrated even to the most purblind and prejudiced. Animals may be seen now coarse and somewhat lathy, imported a few years ago, the third descendants of which are fine, compact, and symmetrical; and others that, in England, were somewhat wanting in constitution, have here completely renovated themselves, and become strong and hardy. If asked to account for these things taking place, I should answer mainly, that our climate especially in the southwest, was better adapted than that of England for the production of neat stock; that our grasses were equally abundant and less watery, and consequently more nutritious; and that our breeders have *some little skill, judgment and taste* in these matters, as well as those abroad.

Herefords.—Though a large and rather a fine, noble looking animal, the Herefords, in comparison with the short-horns are coarse and heavy in the head and horn, with a gathering of thick flabby skin under the jowls, and considerable dewlap. Their loin is well spread, but from the hip bones to the rump they drop suddenly away, and point out like the small of an egg, they also thin off in the flank, and are not usually as well let down in the twist as could be wished. They do not mature as early as the short-horns, and disinterested men were uniform in declaring to me that it took a stronger soil and better grass to support them. This has been denied by the Hereford breeders, but I found the advocates of short-horns very desirous to make the trial by feeding them side by side, to see which should

give the most and best beef on an equal quantity of food.

The quality of the Hereford meat is claimed to be superior—this I doubt, compared to the best short-horns. They are not dairy stock—in what then consists their merits? It is answered the yoke, they make powerful working oxen. But do we want workers alone? and if we did, are we deficient in them? Let the clean-limbed, powerful, muscular, quick-stepping cattle on the hills of the north, the east, and west, answer these questions. And as to their color, I often see those of a beautiful red, with line backs and white faces and belly, in my various perambulations through the states, and have no doubt but they are the direct descendants of as good Herefords as ever graced old England, and long since imported into this country.

But all Herefords abroad are not red, with white faces, &c. Some of the choicest and best that I saw exhibited at the Royal Agricultural Show, and elsewhere, were pure white; others again light roan, with red-tipped ears. I eagerly asked from whence these colors came, as the Herefords are a cognate family of the Devons, which are a deep mahogany red. No satisfactory reply was ever given me. Can I be wrong then in inferring that it was from a short-horn cross, especially as I found the form of these lighter colored animals more nearly approaching that breed than Herefords usually do? If I am correct then in these surmises, where is the necessity of further importations? We can take short-horn crosses on the beautiful brockle face animals that we already possess in our country.

Devons.—The red cattle of the eastern states doubtless originated from the North Devons; and if as much pains had been taken in breeding them in America as in England, they would probably be now as beautiful and perfect. A few very fine late importations have been made of these animals, probably quite enough to satisfy the demand at present. I think them better adapted to the light dry soils of our country than any other breed, the Scotch highland cattle alone excepted.

The South Devons of the same deep mahogany color, I found much larger than those of the north, almost equal in size to the Herefords, and some of them with nearly the fine handling, the loin and quarter of the short-horn. The cows of this breed are not unfrequently very good milkers, giving not only a large quantity, but also that of a rich quality. The oxen are admirable in the yoke, and make excellent beef. To those who have good pastures, and like this style of animal, and cannot rest satisfied with a cross of the short-horns or the Devons already in the country, I would recommend a small importation. I subjoin the size of a bull 3 years and 4 months old, that I inspected among others. Height over the shoulders, 4 feet 10 inches; girth round the heart, 7 feet 9 inches; length from base of horn to end of rump 7 feet, 5 inches. I think he might have been fatted to weigh 13 or 1400 lbs. dead weight. A cow 7 years old, of the same breed, was but a trifle inferior in size.

Sussex.—It is contended by many, that it was from the Sussex cattle that the Devons and Herefords sprung, the former therefore and not the latter, as has been generally asserted, were the pure originals. Be this as it may, their color and general characteristics are much like the Devons, and their weight but a trifle inferior to Herefords, with rather a greater proportionable length of body. The finest specimens are very symmetrical in shape, with limbs clean and sinewy as those of a race horse. I am confident that this style of cattle would rather suit the taste of the south. They are only moderate milkers, but their beef is pronounced unexceptionable, as indeed will that of all well shaped animals be found, when properly fatted, and that are worked in the yoke somewhat, and do not mature till about 7 years old.

It was against this beautiful race, the herd of Mr. Selmes, that Earl Spencer showed his splendid drove of short-horns for a mere nominal wager. Of course the Earl won, but not quite so easily as was anticipated. These animals are attracting considerable notice just at present in England among the graziers.

Jerseys.—The cows of this breed have been much celebrated for the quantity and quality of their milk. No doubt much improvement has been made in them by careful selections, with reference to these particular properties, still a great deal is owing to their high feed on parsnips, a root cultivated in great quantities and perfection in the Isle of Jersey, but after considerable inquiry, I could not find that they excelled the average of our own good native stock in these particulars, when equally well fed. They are of medium size, with short, fine, clear, waxy turned up horns, long clean head, beautiful mild eyes, thin neck, fine limbs and shoulders; but their backs are sharp, and they carry a very light quarter, and bred in so mild and equable a climate, their constitution is delicate, and with so thin a skin, as to make them totally inappropriate to our climate, when the flies of summer would so torment them on the one hand; and the cold of winter pinch them on the other.

Ayrshires.—This is an inferior short-horn in miniature, and I candidly think has been greatly overrated. That it is an excellent cow both for the dairyman and butcher, in the particular district of Scotland that it inhabits, and fed upon their peculiar food, I do not doubt, but when they come to be transported to England, and especially to America, they have not fulfilled expectation in these points. They derived their principal good qualities from a cross of the short-horn bull, these animals we have now among us at a moderate price, and in great perfection, to those therefore, who wish for something like an Ayrshire, already acclimated to our hands, I recommend to save their money at home, and purchase snug short-horn bulls of a medium size, bred here from milking families, and then cross them upon the best native milkers at their hand, from these make the most approved selections, and so continue on, and in this way with a small comparative outlay, a superior race of animals may be grown up throughout our country, better adapted to our use, than any thing we can possibly import. Grade short-horns are abundant now, especially in the west, superior in form for the butcher and milking qualities, to any Ayrshires that it was my good fortune to meet with while abroad.

Red Galloway.—By the above I mean a deep formed, square, bright red cow, without horns, and of these I have seen as fine specimens on the

Jersey marshes opposite the city of New York, said to have been originally imported from Holland, as I believe exist in the world. They were kept there as dairy cows, for the purpose of supplying that city with milk, and had the size and nearly the perfection of form of a snug short-horn, were capital meat well fatted, and rather celebrated as deep milkers. This breed I look upon as particularly desirable, they never can injure any thing by goring with the horn, and wanting these excrescences, it takes away of course just so much offal, and, as I think, adds so much the more to their value.

Black Galloways.—These are essentially the same as the reds above described, existing in the Galloways and other districts of Scotland, and the North of England, but perhaps, as a grazing beast of a higher repute, and are brought up and fed in large numbers from Scotland throughout England. I should like to see an importation in a small way into America of this useful race of animals, for they are active, lively, kind, and quiet in disposition, and superadded to their good qualities of meat, are fair milkers. I have heard them called Highland, and black cattle, simply, as well as Kyloes, Aberdeens, Angus, Keillor, Humlies, &c. There is also another kind of black cattle with horns, that are something of the same quality as the Galloways of the high bleak hills of Scotland. The above are all that struck me as peculiarly valuable in British cattle, and in summing up, it will be seen that we already bountifully possess the elements of good husbandry. We now want to be better informed, what animals best suit the soil, food, and climate of particular sections of our wide extended country, and it is to this point that I would earnestly solicit the attention of breeders in their communications, when treating hereafter on this very important and interesting subject.

A. B. Allen.

From the Southern Agriculturist.

MANURING WITH SALT MARSH GRASS AND MUD, ON THE SEA ISLANDS OF SOUTH CAROLINA.

(Extract from a Report on Sea-Island Cotton.)

No portion of the state is so abundantly supplied with materials for enriching the land as the Sea-Islands. On many of them there is scarcely a plantation of which one or more creeks do not form part of its boundary. The quantity of salt grass, and of mud is therefore inexhaustible. If these were skilfully used, the complaint of failure in the crop, from sterility of the soil, would seldom be heard. Of the former, marsh is not only in every respect superior to the rush, (one of the varieties of the plant of the genus juncus,) but stands pre-eminent as a manure for cotton among vegetable substances. To realize its full value, it should be incorporated with the earth during the summer months—the earlier the better. After the working of the crop has been completed, a certain number of active men are set to work with suitable flats or boats. The cuttings of each day are taken to the field on the following day and immediately buried; or rather a little earth from the tops of the ridges are thrown upon the marsh, which, as the chops with the hoe are not made continuously along the entire line of the ridge, but intervals of six or eight inches of sward are left, is by this process only partially covered. The quantity for an acre is twenty piled cart-loads. If the land be very light, only sixteen loads are recommended, as the blue disease, where it is not sparingly used on such grounds, is likely to be generated, of an irregular season.

Of course on all soils favorable to the production of blue cotton, the application of marsh should be carefully avoided. By the rotting of this grass from exposure to the rains and heat of summer, according to the mode of piling it for future use so generally resorted to, one-third of its nutritious properties is lost by evaporation, and consequently, one-third of the labor and time expended in collecting it—a point which appears to be wholly disregarded by the planter—is uselessly expended. If twenty cart-loads, the amount in general necessary for one acre, be accurately ascertained but not then listed in, when the usual period for removing them arrives, it will be found, that about twelve loads constitute the entire bulk; further, that the growth of the crop will show, that the manure is comparatively of an inferior quality. The task in gathering marsh for each laborer per day is three piled cart-loads. With these data, let us compare the actual results of the two practices, of which winter listings is almost universal. Ten fellows in thirty days will cut but nine hundred loads, which, if buried in summer, will cover forty-five acres of ground. On the other hand, if the operation be postponed until February, the quantity will be reduced to about six hundred loads, or enough only for thirty acres: the gain therefore by the method recommended is equal to the labor of ten men for ten days. Added to this there are incidental advantages worthy of especial notice. At no period is less work done by negroes than during the season for gathering manures. All expedients hitherto adopted to secure a full day's labor have been easily defeated. This plan surmounts the difficulty, as far as responsibility and mutual checks can accomplish it. Every day three sets of workers are separately engaged in effecting a particular purpose—the burying of a certain amount of marsh in a given quantity of land. The listers look to the carters, and the latter to the cutters. By these means, unless the head cartman, who should be selected for his faithfulness, neglects his duty, one and a half acres daily are well manured. Supposing four carts to be steadily engaged in taking away the marsh, and four ordinary females in listing it, the expense of fertilizing the six tasks, or one and a half acres, will be the labor of eighteen hands, of whom three may be small boys, and four mules per day.

The objections to summer listings are, first, that they expose the ground to the action of the sun when its surface should be protected by shade; secondly, that they injure the pasturage; and thirdly, that on very light soils and low lands, where marsh is applied, certain diseases known by the appellations of "blue" and "flaggy" are liable to be produced. In reference to the first objection, it may be remarked, that the tops of the old beds, from the want of moisture, are usually bare. If the mode of taking from those parts of them only a small stock of earth in the manner already explained, be rigidly adhered to,

the injury from this source, if any so decidedly manifest is the benefit of the general practice, is too inconsiderable to be noticed. But it is denied that any pernicious consequences whatever ensue. If there exist for a brief season a partial denudation of a very small portion of the soil, the deposition of a large body of rich vegetable matter under its surface will soon start into existence, if the season be moist, a crop of grass, where the sheep at some period of the day may always be found. The pasture grounds are consequently improved, at least under the influence of marsh, where the proper precautions are regarded.

Whilst it is believed, that no adverse or irregular season has ever been known to produce blue cotton on lands assisted by rotted marsh listed in the winter, if this grass, where an undue quantity is used, be allowed to decompose under the sward by being buried in summer, that disease, in certain locations and under particular circumstances, educed by the weather, will occasionally show itself. The manure in the former state, having parted with most of its exciting properties, is at no time capable of exerting much power; but in reference to the latter, the excess of stimulus from a rapid fermentation during the season of the greatest heat and moisture, increased in proportion to the porosity and friability of the soil, deranges the functions of the plants, and ultimately perhaps destroys their procreative powers. This is the true reason why the lighter the land the greater the probability of danger from the application of marsh in summer. The remedy is obvious. On such soils use this substance more frugally, or with salt-mud, the great antidote to the "blue" poison. In addition to these suggestions, as alike applicable to low grounds, a resort to the spade is an essential auxiliary in preserving the health and arresting the flaggy disposition of the cotton plant.

All that has been advanced on the subject of putting marsh under the ground in summer, applies with greater force to the rush-grass. Its decomposition is slow, and as it contains less aliment than its co-assistant, from seven to eight cart-loads to the task are required. It is a very safe manure, and well suited to any soil. Pine straw is of little value except when well trampled by the cattle. In its crude state it should be put only on the highest and driest lands, as it ministers to the growing crop mainly by collecting and retaining moisture. In aid of this purpose, and to destroy the vermin of which pine-straw is the fruitful parent, the use of salt, at the rate of from one pint to a quart to the task row, will be found eminently beneficial.

Of salt-clay-mud it is not our design to speak at large. Although the best quality—that which has the largest proportion of marsh-roots, contains all the necessary ingredients of the most perfect soil, yet it is true that it gives but an inconsiderable growth to cotton. May not this arise from some circumstance connected with its application to the land? The usual practice is to gather it between hoeing and harvest for future removal, or, if then taken to the field, to allow it to lie there until January or February. In the latter event, the heaps themselves soon exhibit the highest evidence of having incurred a considerable loss, but for this, compensation is erroneously supposed to be made by the facility with which the parts are separated, caused by the exposure of the mud to atmospheric action. When thrown up in winter, it is immediately put in the ground. All its virtues are thereby retained; nevertheless, if the lumps be not thoroughly broken a large quantity of mud will yield but a small quantity of manure. *Ten cart loads well pulverized are of more benefit, than fifteen loads carelessly chopped.* If the mud as soon as collected in summer be taken at once to the field, and there undergo the admitted tedious process of disintegration with the hoe, the chief benefits of the two plans might in a great degree be experienced. The labor of carting and of chopping, if at all, would only be slightly increased, as by this practice a much less quantity is necessary. In any field, which two years before had been in cotton, the lumps of mud will be found in the same state in which they had been put in the ground. The vegetable matter therefore which composed them, it is evident, did not exercise its full power, though to effect that was the design of the planter. How then was the crop assisted? Only by the saline and alkaline properties of the mud, and the small stock of nutriment given merely by the surface of the lumps. If to these benefits, the clay, an essential part of this substance, be made to mix with the soil, which can only be done by pulverization, and the marsh-roots, that ought to constitute one-half of every hoeful, be detached from the mass and cut into particles in order to facilitate their solubility, then, it may be said, that, as a manure for cotton, salt-clay-mud, in a series of years, will realize a greater profit than any other known substance. The neglect of these apparently trifling matters, is probably the reason, why this manure does not materially add to the growth of cotton. As it is of a cold nature, it is never advisable, except where the strength and natural warmth of the land will justify it, to use it alone. In connexion with cotton seed, at the rate of only two and a half bushels to the task, or of well rotted compost manure, one piled basket to the row, its benefit is perhaps duplicated.

EXTRACTS FROM THE SIXTH AGRICULTURAL MEETING AT THE STATE HOUSE.

From the New England Farmer.

Subject, Sheep husbandry. Mr. Fitch, of Sheffield, replied, that if the object is to get *wool*, the Merinos and Saxonies are best; but if *mutton* is wanted, the large, long-woolled are to be chosen. The Saxony is from the Merino. The object aimed at in Saxony was *fineness* of fleece. At present prices, the Merino is more profitable than the Saxony, taking weight of fleece and constitution both into the account. They produce *almost* twice as much. Saxonies will give a fleece of 2 1-4 lbs. which will bring 50 cents. A flock of 40 Merinos, in Connecticut, with which he is acquainted, gave 200 lbs. of wool, or 5 lbs. each, worth from 38 to 40 cents;—the same flock gave 40 lambs. The sheep have every attention and are well kept. Has himself taken 16 lbs. of wool from two Merino bucks. The Merino is more hardy than the Saxony—bears the winter better and requires less attention at the time of lambing. At birth the Merino lambs are clothed—while the

Saxony are almost naked. Fineness of wool is generally an indication of degeneracy—and fineness of hair on the human head indicates the same.

The fineness of Saxony wool has been produced by breeding in-and-in. This course brings degeneracy. These sheep require a close house and much care. The Merino will do well with much less attention. Thinks sheep manure good; and when properly littered they will make more from a given quantity of food than cattle. They improve fields more when feeding upon them.

Mr. Tidd, of New Braintree, asked whether Mr. Fitch had been speaking of *pure* Merinos.

Mr. Fitch. Yes. The Merino will give as much wool as *any other* sheep of the same weight. The expense of keeping is in proportion to *size* the *wool* is in proportion to surface. The solid contents of cylinders are as the cubes of their diameters: the surface is as the squares. So that if the sheep are of equal length and round, the smaller one will have the most surface in proportion to weight. [Let the diameter of one sheep be 2, and of another 3. The square of 2 is 4; its cube is 8. The square of 3 is 9—its cube is 27. The surfaces in these cases are as 4 to 9—while the bulk, weight, or solid contents is as 8 to 27,—showing that there is obviously good ground for Mr. F.'s conclusion, that a larger amount of sheep surface or wool ground can be maintained at the same expense on small sheep than on large ones.—*Reporter.*]

Wool on large sheep is generally looser than on small ones. The small have the most wool in proportion to size. Merino and native cross give good stock of fine constitution—better than Merino and Saxony cross.

Mr. Plunkett, of Pittsfield, said his experience is not much, but he thinks that sheep should be suited to the soil. Small ones are best for hills and short pastures, larger ones for rich pastures and meadows. He can make about as many pounds of fine wool as of coarse on the same quantity of feed. The raising of sheep has not been a very good business lately, owing to the low price of wool—but perhaps it has been as good as most other branches of farming. A cause of the low prices and of need of better protection, may be found in the following statistics.

The growth of wool in the United States is probably not less than forty millions of pounds. It may be assumed that one half of this amount is worked up in our manufacturing establishments.

The importance of this branch of agricultural industry is not only great considered of itself, but in its effect on the other branches of agricultural labor. If the farmers are driven from the wool growing business by low prices of wool, then the dairy and beef growing business will become depressed from over production of those great staples.

It is well known to the farming interest that at the present time the price of wool is very much depressed, and that our wool growers are generally desirous of getting out of that kind of farming; and it might be useful to inquire into all the causes that have tended to this depression.

By the compromise of the tariff question in 1832, all foreign wool costing at the place from whence imported less than eight cents per pound, was admitted free of duty. There was imported in the year ending Sept. 1832, 4,042,838 lbs.; out of this amount were exported 1,227, 959 lbs.; leaving less than three millions of lbs. to be consumed in this country.

The importation of wool has gradually increased since that time. In the year ending Sept. 30th, 1838, there was imported 6,968,365 lbs.; 6,551,128 of which were imported free of duty. In the year ending Sept. 30th, 1839, there was imported 7,824,548 lbs.; 7,398,519 of which were imported free of duty. Only 9,800 lbs. were exported during the same year. Mr. P. has not been able to ascertain the importation of wool in the years of 1840 and '41. We may, however, from known facts about the importation of wool, calculate the amount imported in the last year to exceed ten millions pounds; an amount equal to about one half of what is raised by our farmers in this country to be sold to the manufacturers.

Here we have a principal cause of the great depression of the price of wool at this time.

* * * * *

Mr. Cole, Editor of the Farmer's Journal, has had experience with but few kinds; first had natives—next 7-8 Saxony. This flock gave fleeces of from 4 to 6 lbs. The Saxony, where he lived in Maine, was preferred to any other. The reports of the Agricultural Society of Kennebec county, Me., show that they prefer the South Downs to any others. Pastures for sheep should be high and dry. They do best in dry seasons. He has never seen them drink in summer. In winter they will drink oftener than cattle. Clover hay is good feed for them. Roots are excellent for them in winter, but they should not have many potatoes just before lambing; better then to give some grain. Evergreen boughs are often given and answer a good purpose in feeding. The manure is better than most other kinds. (L. Peters, Esq., of Westboro', inquired what kind of grain he would give.) Does not know whether corn or oats is to be preferred, but would grind in either case.

Mr. Moseley, of Westfield, has found the Johnswort poisonous and troublesome to sheep when he gives them salt, but not so when salt is withheld. Ten sheep, with him, require two tons of hay worth 24 dollars; can get 12 dollars worth of wool and 12 of lambs; and by throwing in the pasturing come out square:—that is the way farmers are getting rich. Their manure is good. * * * * * *

SCRAPS OF FARMERS' CONVERSATION.

Reported by the Editor.

Recently, though at different times, I met and conversed with three farmers, who, in remote situations and under very different circumstances, have made remarkable improvements by enriching land and improved cultivation, and have also reaped large profits from their improvements and farming in general. The subsequent comparing of some of the opinions expressed by these successful improvers, induced the belief that even a very imperfect statement of them, and some of

the particulars of their different practices, would furnish interesting matter for the consideration of others. As there was no intention of this at the times of conversation, and no notes made, it is very likely that mistake or forgetfulness may now cause some errors of statement. If so, I shall be glad to be corrected, and also to be fully informed in writing, for publication, on every part touched on. Should such be the result, even my misstatements by mistake may produce light, and render service heretofore withheld from agriculture. For two of these very intelligent and successful farmers (though long-continued and approving readers of the Farmers' Register) have never contributed, directly, a single line to the pages of this publication; and the third, though he has done much more in that way than most other subscribers, by furnishing several valuable communications, still has *not* communicated near as much of valuable facts ascertained, and observations made, as he might have done, from his abundant resources.

Mr. William Old's farm is in Powhatan, and forms part of a very remarkable strip of peculiar and good soil, which extends not only through that county, but also Nottoway and Goochland, and perhaps still farther. This strip was originally known as the "oak land," it not having a single pine among its forest growth. The strip varies in breadth from 5 to perhaps 15 miles, and was, before being cultivated, much richer land in general than the land on either side, or elsewhere in that region. After long cultivation and great exhaustion, and turning this land out of cultivation, it then throws up a growth of pines, a short-leaved kind, [and of course not the "old-field pine" of the tide-water region.] Mr. Old has a large body of this worn-out and now pine-covered land. But it is not of value for furnishing vegetable matter, as the acid pine lands are. The leaves there never cover the ground thickly, and seem to rot much faster than elsewhere. [This is an interesting confirmation of the doctrine of the antiseptic quality of *acid* soils. This soil not being acid, cannot preserve on it several successive crops of fallen pine leaves, as do acid soils.]

Mr. Old's singular two-field rotation of oats and tobacco, alternated continually, was described by one of his neighbors last year in the Farmers' Register, (p. 308, vol. ix.) The oats are suffered to fall and remain on the ground as manure for the succeeding crop of tobacco, and are found fully sufficient alone to maintain the high degree of fertility necessary for good tobacco crops. All the lots for tobacco are thus managed. Desiring to increase the crop of wheat, at one time this two-field rotation of the tobacco lots was changed to a three-field, of 1st, clover, 2d, tobacco, and 3d, wheat. But the frequent failures of wheat caused this plan to be subsequently changed to the previous oat and tobacco two-field rotation, which has been thus but lately restored. In these two rotations, and without other manure than the oats or the clover, (after the first enrichment of the land by other manure,) one part of the lots has been 17 years so cultivated, without deterioration of the land or its products. The land on which all this tobacco cropping is done, is of broad "creek flats," or low-grounds of smaller streams running into the Appomattox, (the farm does not extend to the river,) and the soil was originally very rich, though shallow. It was, as elsewhere, much impoverished by exhausting and injudicious cropping, before coming into Mr. Old's possession; but, as the result shows, is capable of being restored to fertility, fully and profitably, by self-manuring by its own growth, or by other putrescent manures applied.

Gypsum is used generally, and acts well on the high land, once in each course of crops, which is the five-field rotation of 1, corn, 2, wheat, 3, clover, 4, wheat, (on fallow,) 5, clover. *On the originally poor parts gypsum has done no good.*

Mr. Old is altogether opposed to the practice of graduated ditching on hill-sides, generally through a farm, for the purpose of preventing the washing of the land. He uses some short ditches of this kind, on very favorable positions, and as merely a partial preventive. He has seen land thus treated, which the ditches alone spoiled more than all the washing could do in a century of other judicious cultivation; and which was far more disfigured and injured afterwards, by the water breaking over the banks, as it certainly will do, with all the care that can be used. Supposing even (what is far beyond the truth) that the best arranged and constructed ditches, *always kept in perfect order*, could effect their designed purpose, of carrying off the redundant rain-water, it would be impossible, by any farmer's care, to prevent accidental and unlooked-for stoppages, which would be first made known by turning out the water of a ditch, cutting a gully, breaking by the accumulated force across the next ditch and bank below, and increasing its track of devastation thence to the bottom of the descent. As an example of the insecurity of the system, he referred to one of the graduated ditches, (such as above-mentioned,) through his corn-field, which being short, and frequently under his eye, he had several times himself examined throughout its whole length, and with a hoe removed every commencing obstruction. This care was in addition to all general superintendence and repairing. Late in the year he found that the water had broken over, and had begun to cut a gully. The cause was, that the fodder not having been gathered on a part of the adjoining corn, as it decayed on the stalks the small light bits had been blown off by the wind, and some had fallen in the ditch. The first rain floated this light stuff along the ditch, until a straw or small root, or some such thing, caught and stopped a few bits, which served to stop more; and as the muddy water settled and filled the crevices, finally made a dam sufficient to throw out the water. Had this ditch been at the top of the hill, and several other ditches below, this slight cause would have broken every one, and with more and more damage at every successive breach.

The frequent and generally increasing disasters and failures of the wheat crop in the middle part of Virginia. Mr. Old is at a loss to give a reason for. If he had judged merely from his own land, he would have ascribed it to the use of gypsum, and its supposed power of attracting moisture to the soil, as well as otherwise giving increased succulence to the growth of wheat.

Mr. Old considers that all dry arable land, even though clayey or stiff, requires grazing, to trample and consolidate the soil. He does so once in every course, and keeps a large stock of cattle,

(from 90 to 100,) for the benefit of their manure, and their periodical grazing, more than for any thing else. Besides this temporary use of his clover fields, he has a large standing pasture. He does much of his winter manuring by moveable pens, changed every week. This is done throughout the winter, during all weather in which the land to be so manured is either dry or frozen. Corn-stalks are hauled in and scattered for food and litter of each pen the first half of the week, and straw the latter half; so that the stalks may be as much trodden as possible. The size of the pen, as well as its continuance, is suited to the number of cattle and the quality of litter, so as to properly manure the space inclosed. Bushes are sometimes used to shelter the pen somewhat from the cold winds, but not generally. This mode of manuring saves much hauling, and is in other respects deemed as profitable, as from the permanent farm-yard, where the cattle are kept during all wet weather.

Gen. Peter H. Steinbergen is a farmer, and still more largely a grazier, in Mason county, on the border of the Ohio. The great object of his cultivation and great means of profit is grass to feed and fatten cattle for market. His enriching his exhausted lands by *top-dressing* presents the most successful, as well as extensive practice, in that novel and as yet much doubted mode of applying putrescent manures. The practice of the graziers in that part of the country is to manure by littering and feeding in lots, changed as often as sufficiently covered, and also on grass land. Of course, the manure is necessarily applied to and remains on the surface, and its early benefits are given to the grass, and not only for that year but for as many after as the grass may continue good, or the general plan of cultivation may permit the field to remain free from the plough. But great as has been the improvement thus made on land previously reduced very low by exhausting tillage, Gen. Steinbergen is fully convinced of the truth, that the ability to enrich poor land by putrescent manures alone, depends on the land having been originally fertile.

Gen. Steinbergen, without estimating red clover lower than its universally admitted degree of value, thinks still more highly of greensward, [*poa pratensis*]; and the superiority he claims for the latter is not only as furnishing more palatable and nutritious food for cattle, but also as a much richer green manure to the land producing it than clover. On describing to him how the sandy lands of lower Virginia, after marling, became sprinkled with greensward, he said it was then in the very state when (to nurse this grass and obtain its rich benefits) tillage should be delayed as long as possible, and the land be subjected to grazing instead. He thinks that light land should be always grazed and trampled, at least one year before tillage—and stiff land designed for tillage should never be grazed.

Dr. Corbin Braxton cultivates the very sandy low-grounds of the Pamunkey, where he has made most extensive and profitable, as well as very remarkable improvements of product, by marling with the green-sand marl—which has both the fertilizing principles of green-sand and of calcareous matter combined. As his general results, and also a general description of the Pamunkey lands, have been already published at length, (at pp. 678 and 637, vol. 8, Farmers' Register,) they will not be repeated here. And hereafter will be added some additional observations on that most valuable body of manure, and its remarkable effects. Here will be given merely a few of less important matters of conversation, and answers to verbal inquiries, though generally on subjects then under the eyes of both parties.

The opinions of all three of these farmers concur fully in the absolute necessity of sometimes grazing light lands. They also agree in the certainty and profit of enriching by putrescent manure originally rich land—or, in Dr. Braxton's case, of poor sandy land after its being marled. He has found, by experience, that it is best to graze clover pretty heavily, but still leaving a cover of (say) ankle high, the year he fallows for wheat. These very light lands, so light as to be worthless for wheat without marl, when marled and with clover fallow become good wheat lands—the best crops yielding 20 bushels the acre. After corn, the wheat is very mean, and indeed scarcely worth sowing. The Hessian fly is sure to be very injurious to corn-field wheat. The best safeguard against this insect is to enrich the land and thereby to cause the wheat to out-grow the depredations of the fly.

Before marling, all the efforts made to enrich by putrescent manures availed but little. Though all these light low-grounds were supposed to have been originally rich, farm-yard manure served to do but little good, and the effects were very fleeting. Since marling [as on all other marled lands] precisely the reverse is the fact.

Dr. Braxton is about to try to have clover to succeed his corn crop, instead of wheat after corn (as usual) and clover after wheat. This would doubtless be a capital improvement, provided clover can be produced with certainty after corn. In answer to my objections stated, of the attempt being made, for several years, in experiments at Coggins Point, Dr. Braxton considers that the Pamunkey land becomes, by the use of its peculiar marl, so favorable to clover, that there will be no difficulty in having it after corn. After clover being once sown, and the land full of seed, it takes possession of it whenever it is without cultivation, as if the most natural product of the soil. He is opposed to fall or early winter ploughing of the land, when preparing for corn. Ploughing in spring serves as well, and saves some after-tillage, which the more consolidated early ploughed land would require; and moreover, the early ploughing is thickly covered by spring with young clover, all of which is killed by the first tillage. Later ploughing would cause much less seed to germinate, and be therefore destroyed.

The Eastern Shore bean grows very kindly on these lands, after marling, and instead of being prized as an improver, is denounced by Dr. Braxton as a worthless weed, obstructing the growth and lessening the product of clover, the great green crop for manure, which he values far beyond all others as an improver.

Dr. Braxton esteems the ruta baga turnip crop very highly, and deems the sugar beet as comparatively worth very little. Besides the value of the ruta baga crop, for stock, when secured, he thinks its product almost certain, on his land, with proper management.

When on his farm in November, 1840, I saw a

novel mode of following ruta baga by wheat, or rather having both crops growing at once. On a rich part of the clover land fallowed for wheat, ruta baga was planted in rows 4 feet apart, and cultivated by ploughing and weeding. In October, when a fine growth of turnips was on this patch, (though no manure had been applied, except the green clover turned under,) wheat was sown here at the same time with the adjoining part of the field, and the seed ploughed in, between the ruta baga rows. The roots were afterwards taken up, when grown and required for consumption. Dr. Braxton left home before the wheat was reaped; but from its previous appearance, as well as his overseer's report, he thought the product not much lessened by the growth of turnips.

OBSERVATIONS AND ROUGH EXPERIMENTS. 1841.

For the Farmers' Register.

1. *Gypsum.* On March 26th, 21 bushels of pulverized gypsum (French) sown at the rate of a bushel per acre on clover of second year's growth. Soil, originally acid and very poor; a light loam on sandy subsoil, well marled in 1824, since manured, and altogether improved, from a product of 6 bushels of corn per acre to 25 or 30. The clover crop mean, and after June 1st, freely grazed. No benefit whatever perceived on a comparison with the adjoining clover not dressed with gypsum on a soil exactly similar.

2. *Green-sand.* At the same time, in the same field, on similar soil, and on clover of same growth, one acre dressed with 40 bushels of green-sand earth (not calcareous,) from James river. No effect produced.

3. In March, eight acres of good loam, marled 10 years ago, product in corn supposed equal to 30 bushels, and in wheat after clover 18 or 20 bushels, were dressed with green-sand earth at the same rate. Two beds left out. Clover in its first year. No perceptible benefit.

4. *Seed wheat.* Having seen *old* seed wheat recommended, by several contributors to the Register, of the crop of 1840, the grain of which was very good, a small quantity was kept in good order and carefully guarded against all danger of heating, or other injury. This fall, 12 bushels sown in a field of uniform and good quality, and immediately adjoining *new* seed of same kind (purple straw.) The sowing of both kinds commenced and finished in the same day, and operations in every respect conducted exactly alike. Quantity to the acre the same (5½ pecks.) The old seed *a little* weevil-eaten, notwithstanding every care used in keeping it, but not enough so to be much objectionable. The old seed longer germinating, and to this day, December 31st, looks decidedly inferior to the wheat from new seed.

5. *Top-dressing with farm yard manure, and with unprepared leaves.* Eighteen acres of light sandy loam in clover of 2d year, very thin and very unpromising, was top-dressed in April, 1840, with rough and unrotted manure from the farm-pen, at the rate of 800 to 1000 bushels per acre. This land was marled in 1821, and though greatly improved, (for before its product was 8 to 10 bushels in corn, and perhaps 3 in wheat,) was still but of middling product, and before this manuring, would not have brought more than 18 or at most 20 bushels of corn per acre, or 6 bushels of wheat after corn. The last crop of wheat, cut in 1839, after corn, was known to be only 42 bushels of wheat or 2⅓ bushels to the acre. That crop however was very much damaged by chinch bug. The top-dressing was as coarse as any trodden litter could be, many corn-stalks merely mashed, but unbroken, constituted an average of the manure of the farm-pen, which was made of the stalks and straw of the farm-pen trampled by the cattle, and covered over with the manure of the stables and hog-pens every time they were cleaned out throughout the winter, which was about once a week. The hog-pens were principally littered with leaves from the woods. The effect of the top-dressing on the clover was almost immediately perceptible. In September the field was fallowed for wheat, and in June of this year 283 bushels of wheat were cut from it, equal to 16 bushels per acre. The soil is decidedly a corn soil, and too light for wheat. But the most striking and gratifying proof of improvement is the frequent appearance of green-sward in many places, where it was not at all observed prior to this manuring. This valuable grass has generally made its appearance in spots in the different fields after marling, but this particular field was too poor for its growth (so as to be noticed) even after marling, until it received this top-dressing.

6. In January, 1840, about 15 acres of light loam, with sandy subsoil, in clover of second year's growth, top-dressed with 377 very large ox-cart loads of leaves, principally pine-beards raked together in adjoining woods. The covering was so thick that at one time it was thought that the clover was in great danger of being smothered. It however came through and was decidedly benefited, except in spots where the leaves were left too thick. In the fall, the whole was fallowed for wheat. Crop 15 bushels per acre, and considered a good yield for the land. Its product after corn has usually been about 8. Part of this land was much infested with wire-grass. In getting in the wheat no means adopted to get rid of wire-grass, except to pick up and carry off the little that the harrows brought to the surface. And in fact this piece received one harrowing less than I usually gave to such wire-grass spots, on account of a rain which interrupted the operations. This fall, 1841, in ploughing for corn, noticed that very little wire-grass was left. Could the leaves have had any agency in killing the wire-grass, by shading or otherwise? Or did the mere exposure of the roots to the sun, as some maintain, effect it? Some credit is no doubt due to the latter cause, but the former has a strong, and, may be, a stronger claim; for, in similar spots, fallowed without any application of leaves, I have never known a similar decrease of wire-grass. It may be well to mention that the above 15 acres were 10 or 12 years ago well marled—the soil, originally and previously to marling, acid.

7. *Leaves ploughed under.*—In January, 1841, covered a stiff, intractable soil, previously and some years ago well marled, with leaves, which were ploughed under, and oats sown early in

March. No benefit to the oats whatever; and when ploughing the land for wheat this fall, the leaves were turned up very little decayed.

E. RUFFIN, JR.

[The foregoing statements were furnished upon our suggestion, and in regard to most of them in consequence of our seeing or otherwise knowing the general results, and deeming them the more worth notice, because of our personal acquaintance with the original condition and character of the land, which was the subject of our own early labors and improvement by marling. Though the written memoranda of the writer furnished the by-gone but recent facts nearly as here stated, still, as *accurate experimenting* had not been at first designed, and still less any publication of results, it is not pretended that the statements of quantities are entitled to the respect due to the results of carefully and properly conducted experiments.

We have another and more general reason for presenting these notes of observation to our readers. It is to show that by merely noting down, in the most concise and simple form, any results or facts observed deemed worth remembering, any practical cultivator might aid in furnishing a mass of interesting facts, or suggestions of subjects for inquiry and more careful experiment. There are hundreds of our readers, who never report any thing for publication, who might in any half hour, furnish some few such observations, which, *as facts*, and still more as having the authority of the name of the observer, would attract general attention, and convey much of useful suggestion, and induce imitation and co-operation in the pursuit of doubtful truths—all tending to cause the making of properly conducted and accurately reported experiments. Will each one reader, who may acknowledge the value of such operation and results, do something towards producing them?—ED. F. R.]

For the Farmers' Register.

LIQUID MANURE.

In the December number of the Register, I notice detailed a number of interesting and conclusive experiments, make by Mr. Milburn of Yorkshire, in the application of liquid manure. In the fall of 1840, after cleaning out my standing farm-pen for the winter reception of my cattle, there was left in it a quantity of dark rich liquid, which I felt inclined to apply to a neighboring field, then in young clover of first year's growth. With much the same primitive contrivance of pails and barrels placed in tumbril carts, as used by Mr. Milburn, I contrived, with much inconvenience, to get out most of the liquid. It was spread very unequally, and I cannot say at what rate. In many spots where the application was too heavy the clover was killed outright, but was succeeded the next spring by a most luxuriant growth of weeds. Generally, however, the clover was much benefited. This fall the field was fallowed, and sown in wheat. On the part where the liquid manure was applied the wheat now exhibits a decided superiority. I have no sort of doubt of the highly enriching quality of the liquid, and of the great annual loss suffered by our farmers when it is allowed to run off into the nearest gullies, or carefully drained off to the adjacent ravines, in order to render the working of the manure more comfortable to the hands. In every properly shaped farm-pen, each spring and fall, when it is cleaned out, there will always be found a large quantity of this valuable liquid, which can be easily carried out by the simple contrivance recommended by Mr. Milburn. I think this single article, above referred to, is worth to every reader of the Register, who will adopt and act on its suggestions, more than the subscription to its whole series. Z.

Jan. 6, 1842.

ON SOILS.

From the American Farmer.

Mr. Editor:—Will you accept of a few hasty and indigested remarks on soils and their properties of production? Such as they are, they will be very much at your service; but I must claim for them the indulgence of yourself and readers, as they are written *currente calamo*, and without being transcribed or copied.

In the American Farmer, No. 38, of the current volume, I observe that you have copied a short article from the Encyclopedia Britannica, concerning a very fruitful soil in the county of Caithness.—Such soils have been found, in the alluvial formation, in different parts of the globe—such is that of Ormiston, in East Lothian; such is that of Somersetshire, in the low lands, near the opening of the river Parret into the British Channel; some of the lands of East Florida, possess the same properties; and to come nearer home, some of the land of Spesutia Island, in Harford county, possesses the same inherent quality of production.

Now as to the theory, by which this extraordinary fertility is explained, in order to form a rational and correct one, we must take into view all the connecting circumstances. The soil described by the writer of the article under consideration, is said to consist almost entirely of broken shells and fine mould, the latter in almost an imperceptible proportion—that from Ormiston afforded, by analysis, eleven parts in the hundred of mild calcareous earth, twenty-five of siliceous sand, forty-five of finely divided clay, nine of animal and vegetable matter, and a small quantity of phosphate of lime, to which latter its fertility is in a great measure attributed.

The soil from the low lands of Somersetshire has been found to consist of only one ninth of siliceous sand, and *eight ninths of calcareous marl*, with five parts in the hundred of vegetable matter; *and its fertility is attributed to its power of attracting principles of vegetable nourishment from the atmosphere, and from water.*

Much of the secret of fertility of soils consists in their power of attraction, &c., as observed in the foregoing paragraph. All soils are not capable of being rendered thus *artificially* fertile—much will depend on location, whether level or undulating—much on the structure of the sub-soil and its capacity of retaining moisture; and where there is not an approximation to correct proportions, essential to fertility, the labor and expense of rendering them fertile would not be counterbalanced by their productiveness.

The attractive or absorbent property of soils has probably not been sufficiently attended to—that lime, in some form, is essential to the fertility of soils, and to their power of absorbing nutriment from the atmosphere, all experience testifies; and it is that portion of the soil which, next to vegetable mould, is most subject to loss, as well by its affording an essential part of plants, as by being gradually washed away by rains, &c. In illustration of this latter process of waste, I will mention a circumstance that has lately come within my observation. Last fall, in November, I had the roof of my kitchen covered with a thick wash of lime. A north-east storm came on before it got dry, and washed a considerable portion of it off. A window was so situated as that the droppings from the eaves were driven against it—these droppings held the lime in solution, which was beautifully crystallized on the glass—this may serve to show that the calcareous part of soils is gradually wasting. Nearly all grains contain a portion of lime, some a large portion; and they can obtain it in no other way than from the soil.

From the foregoing observations it must be apparent, that in such cases where the soil does not originally contain a large portion of lime, it will be proper, occasionally, to renew the application; and I am decidedly of opinion, that when it is intended to apply one hundred bushels to the acre it should be applied at three or four different dressings, at intervals of three or four years, as by this mode the greatest advantage will be obtained, at a given expense.

Some plants, more than others, possess the power of attracting from the atmosphere the substances essential to their growth. The house-leek, (*sempervivum,*) is a remarkable instance of a plant possessing this power—such plants, it is presumed, contain but little lime. Not only plants, but some animals of a low grade of organization, possess the power of attracting substances from the surrounding elements, essential to their growth—the oyster is an instance of this—without the power of locomotion, attached to a rock, the sperm of the oyster has the power, not only of attracting all its food from the surrounding elements, but of forming a calcareous shell for its future habitation.

But to return to a consideration of soils: it must be apparent that they should, in order to be fertile, be made to contain the food of plants, and at the same time be so constituted that they should possess the power of attracting it from the atmosphere. Many of the articles that have been found to contribute greatly to the growth of plants, cost the farmer too much, and they are of too transitory a nature. Such are *crushed bones, and poudrette*; substances, imparting astonishing fertility for one year, and where they are within a reasonable distance of transportation, will pay in one crop. It has been thought, and I should like to have the experiment fairly made, that ground oyster shells would answer nearly the same purpose of ground bones—oyster shells, though affording pure lime by calcination, differ, essentially in their properties from lime-stone. They are composed of a carbonate and phosphate of lime, and contain a portion of gelatine, or fibrine. It is hence concluded that while they would, when ground, act almost as quick as crushed bones, they would be more durable, at one third, perhaps one fourth the expense.

The most astonishing and negligent waste is attendant on the city of Baltimore, in permitting for years the essential material for *poudrette* go to utter waste and loss. Many thousand dollars are thus annually lost for the want of knowledge and enterprise. No speculation that could be entered upon at this time, would be so sure to reward its undertakers as the manufacture of poudrette in or near the city of Baltimore! Individuals have probably been deterred from entering upon it by the elaborate descriptions that have been given of the process, and the apparently large capital necessary to carry it on, whereas nothing can be more simple than the process, and no business so sure of extensive profits that could be conducted at so small an expense. It is to be hoped that some enterprising agriculturist will take the hint and make a princely fortune by it.

From the great difference of the causes that influence the productiveness of lands, it is obvious that all the favorable circumstances are rarely found to be united in any soil; but by a due attention to the component parts of soils, by chemical tests, by careful observation and experiment, we may generally be enabled by adding such parts as are deficient, to give fertility to those that are naturally sterile. It is to the earthy parts of a soil that we are to turn our first attention, and when these are formed in due proportions, its fertility may be considered as permanently established. The animal and vegetable portions are but temporary, and are exhausted by a given number of crops. Those soils must be considered best which contain the greatest store of those principles that constitute the food of plants, permanently inherent in their quality—Calcareous soils, by their constant attraction for carbon are of this class; and if they at the same time contain animal and vegetable substances, are more eminently qualified for this purpose by the supply of carbon and hydrogen which they afford. H.

Wood Lawn, February 14, 1842.

REMARKS ON A PRECEDING COMMUNICATION ON BERKSHIRE HOGS.

We are so well pleased to have so judicious and practical a farmer as the Rev. J. H. Turner, for the first time a contributor to the Farmers' Register over his own signature, that we have no inclination to find fault with any thing he says, or to defend our editorial course from his strictures. But respect for himself forbids our passing over his remarks in silence.

If it were not that our intelligent and highly esteemed correspondent had so much mistaken our remarks, at page 17 of this volume, we should deem it sufficient to refer to those remarks for our defence against his charges. It is strange indeed that we may not dare to denounce humbuggery, even where every intelligent and candid observer will admit it exists, without being deemed an opposer and enemy of the really valuable improvement on which the humbug is built. We have repeatedly, and especially in our remarks in question, admitted our belief in the Berkshire hog being a valuable breed, and of course its introduction and diffusion being an important benefit to agriculture; and so far as our interest is now connected with practical agriculture, we have acted on that belief, by beginning to raise Berkshires, though thereby supplanting another previously very highly prized breed. Nevertheless, this favorable opinion is not incompatible with another, to wit, that this breed of hogs has been praised and puffed much more than it deserves, and to subserve the self-interested views of salesmen; that there has been a deal of puffing, falsehood, and deception, for this same end, and that too practised by some of the most noted breeders and salesmen; and, in short, that there has been so much humbuggery practised in this respect, by those salesmen, that they, while filling their pockets at the expense of their dupes, have almost stifled the truth, and hid the real value of the breed, by the overlayings of falsehood. We know how much mankind dislike to be made to know that they are cheated; and that he who cheats them will always fare better in their opinion than he who endeavors to expose the cheat. But while we expect, and are resigned to the fate of getting "more kicks than coppers," or more curses than thanks, for our attempts to expose humbug, it is inconceivable to us how such a man as Mr. Turner can so far misconstrue our course and its object, and consider us as opposing true improvements of stock, or improvements of any branch of agriculture, because we oppose, and try (vainly) to expose, those who are perpetually using such real or alleged improvements to make dupes, and obtain ill-gotten gain for themselves. When we have to seek for the true benefactors of agriculture, it will not be among the Bements and the Lossings, any more than the Thorburns, the Physicks, the Princes and the Morrises.

Absence from home, when the letter of Mr. Turner was put in type, prevented these remarks being placed at the close of his communication, as would have been more appropriate.—Ed. F. R.

THE ADAPTATION OF PARTICULAR WHEATS TO PARTICULAR LOCALITIES.—PATENT MACHINES.

For the Farmers' Register.

In a late number of the Register, Mr. Carter suggested the benefit to be derived from the change of seed wheat. On a former occasion, I endeavored to draw attention to this subject, and finding that it has now attracted some notice, I shall give an account of the wheat most successfully grown here. From my early recollection till the year 1798, when the Hessian fly first made its appearance in this district of country, the white Washington was the general crop. Its destructive ravages induced many farmers to try other varieties; but it was soon found that this pestilent insect made little distinction. The late Col. Edward Hays, of Talbot, who was much devoted to agriculture, and fond of experiments, for some years abandoned the growth of Washington wheat: he afterwards got seed of me; and said, at a later period, he had tried many varieties, but had found none so valuable, and productive, as the Washington wheat. The grain is white, and makes the best family flour; the straw is soft, and both horses and cattle prefer it to any other wheat straw. It only grows well in salt-water districts. If carried into the interior it degenerates, loses its color, and becomes chaffy. For the last fifty years to which my recollection runs, this has been the principal crop on the farm where I now reside, till last year. About six years ago, supposing that changing seed with a neighbor might be beneficial, I got a few bushels of the same sort of wheat. Though he was ignorant of it, his wheat contained a small portion of smut, which soon infected all my white wheats; and after some fruitless attempts to clean it, I was under the necessity of abandoning its growth. Some of my neighbors, who have suffered in the same way, are now raising seed picked by hand, and as soon as I get pure seed, I shall sow it again. I have supposed this wheat would suit on some of the salt-water districts in Virginia. About thirty years ago, a wheat was introduced here, and is known by the name of the red chaff beard, I apprehend the same mentioned by Mr. Carter. It seems adapted to a variety of soils, and is more generally grown in this county than any other. It ripens early, though sown late; and suffers less by the frost, especially on low, wet grounds. For these properties, it has been part of my crop for many years, though it sells at a much inferior price in the Baltimore market. When my white wheat was infected with smut, though this was thrashed by the same machine, cleaned with the same fan, and stored in the same granary, it did not contract the disease. An experienced farmer, to whom I mentioned this circumstance, informed me that his white and red wheat had been equally infected.

A farmer always incurs risk by changing seed. When I abandoned the growth of Washington wheat, I purchased white flint from a gentleman in the neighborhood, who got the seed from New York in 1836, and had grown it exclusively on his farm. He had no suspicion of smut; but upon careful examination, I found it to contain a small portion, and declined sowing it. I then procured Pennsylvania white wheat, which has been lately

introduced here: it does not ripen early, and I do not think produces equal to the Washington, or red chaff.

I last summer saw some Chester county farmers in Washington, who stated that they grew there a wheat which they called the Mediterranean, which, though sown the last of August, would resist the Hessian fly. Dr. Darlington, a gentleman of science and intelligence of West Chester, confirmed their statement; and I purchased a few bushels, which I have sown for experiment. I have also sown a small quantity of white wheat which I procured from Owego county. It has a fine white grain, and much resembles our Washington white wheat.

From reading, and not from experience, I have been induced to think, that the change of seed wheat is beneficial. The Scotch farmers often import seed from England, and Scotchmen generally understand their business. I cannot undertake to say that the white Washington or red chaff beard has degenerated on my lands; on the contrary, when the season is favorable, I have found them equal in weight and product to what they were in my earliest recollection. My theory is, that there are certain soils to which particular varieties of wheat are best adapted, and when this is ascertained, it is always safest to rely on those varieties. If it be true that wheat adapted to a soil degenerates from long sowing the same seed, raised from the same ground, I should prefer the same variety from a remote place. I have seen some beautiful parcels of wheat brought into this neighborhood, which very soon degenerated. Some years ago, Judge Thomas Buchanan sent me, from the highlands of Washington county, some beautiful white wheat, from which I had formed high expectations; but it very soon degenerated, which I attributed to its not being suited to this soil. Upon the second introduction of red wheat, after Mr. Carter had ceased to sow it for fifteen years, he found it to produce well; and when the product first diminished, it is probable if he had gotten seed of the same variety from a distance, he would have derived the same benefit. The adaptation of certain varieties of wheat to particular soils is proved by the Washington wheat growing in salt-water districts, and degenerating when carried into the interior. Mr. Carter illustrates the necessity of the change of seed wheat by analogy to animals. It is now generally agreed that horses, cattle, sheep and hogs degenerate from long exclusive association. If from this cause a herd of Durhams had depreciated in value, I apprehend if one of the same herd was introduced when the connexion had been long broken, the cross would be as beneficial as if made by a Devon. I am well satisfied that the white Washington and the red chaff wheat are best adapted to my lands, and though I am not sensible they have degenerated, I should be pleased to get seed of both or either from a distant region, for experiment.

The community stands much indebted to Mr. Garnett, for his persevering efforts in the cause of agriculture; and I am pleased to find that an agricultural convention has met in the city of Washington, which has framed a constitution, and organized a society; though, I much fear, it will languish for want of funds. Agriculture, though the paramount interest of the country, and extending into every section, it seems is not so connected with *the general welfare* as to be entitled to the countenance of the general government. Perhaps one of the causes is, that no demands have been made. If I was a member of this society, I would bring the subject before them at their next meeting, to see if something could not be made out of this clause of the constitution. The manufacturers, though for the most part a sectional interest, placed themselves under its fostering wings, where they would still have remained, but for the ardent and determined spirits of the south. I am not a latitudinarian in construction; but there are many problems in agriculture not solved, many discoveries not assayed, for want of means, and I think an appropriation to these objects would be more for the general welfare, than sending ships on discovery to unknown seas, even if they should be so fortunate as to find an island within the Arctic circle.

Among other new discoveries, the wheat drill was presented last year. The patentees are Pennsylvanians, from Chester county. They stated that, in their richest lands, one and a half bushel had been found sufficient seed; on my improved grounds I generally sow two to the acre. I had a few acres put in at the rate they proposed, alternating spaces, with the plough, in which I sowed two to the acre. The next harvest will test the accuracy of their statement. I kept the time of the work done by the drill, for two successive hours, and found it would plant one acre to the hour, with two men and two horses, without fatigue to either. It deposites the wheat and covers it by the same operation; and none can be found on the surface. The saving in labor and the saving of seed are no small considerations. I was much pleased with the work done by the drill. It is somewhat complicated, and I have not sufficient information in mechanics to determine on its stability, and whether it can sustain the rough usage of rough hands.

It appears to me that there is great defect in the patent law, and I think the subject not unworthy the consideration of the National Agricultural Society. The commissioner is directed to award a patent if the machine or composition of matter *be new and useful*. By examining and comparing a machine with the models in his office, he can determine if it be new; but he has not the science, experience, ability, and means of experiment, to determine on its utility; which does not depend only on its apparent fitness for the work intended to be performed, but its ability to sustain it in continued practical operation. I do not speak from any personal knowledge of the master of patents, but it would be rare to find a man possessing all the requisite qualifications. The Patent Office ought to have attached to it a scientific practical chemist, and a scientific practical mechanic, (with salaries to command the best abilities,) who should be provided with full means for experiment. In the departments under the general government, where the general welfare is concerned, no reasonable expense ought to be spared. Patent machines and patent medicines have long been a gross imposition, and must so continue, until the Patent Office shall be put under better regulations. If the wheat drill had passed through the Patent Office under the inspection of men competent to decide on its usefulness and durability, though the price is $100, I would purchase one for the next

season ; for I entertain no doubt but the saving of labor and seed in two crops would clear the cost.

WM. CARMICHAEL.

Wye, Queen Ann's, Md., Feb. 17, 1842.

ADDRESS TO THE AGRICULTURAL SOCIETY OF MASON, CABELL AND KANAWHA.

By Gen. P. H. Steinbergen, President.

Gentlemen of the Agricultural Society:—Let me congratulate you that we have again assembled under the rules of our society. It affords evidence of continued zeal to the cause of our association, and furnishes at the same time an opportunity, highly pleasing, of friendly social intercourse among its members. Such meetings are well calculated to give life and animation to the prosecution of that great interest in which we are engaged. By means of premiums to successful competitors, we can tempt the spirit of rivalry, and stimulate to increased exertion.

The farmers of this nation are the sheet-anchor and support of every other great interest of society. On their broad shoulders rests the superstructure of national wealth and prosperity, and to their success or failure you may justly look, as to an unerring index, for the condition of the whole community. How important then it is to us, that we should possess the lights of experience, in order to guide our operations! How important that those operations should be conducted upon settled principles, drawn from well authenticated facts, suited to our local circumstances. I hope that several of you the past season have given your attention to this primary duty, and will report to this meeting such actual experiments as you have made, and believe conducive to our interest. If every member would pursue such a course, we could soon make a depository of useful information available alike to all.

During the last summer some facts came under my own observation, that have peculiar and appropriate relations to the condition of our country. I had always supposed that the soil of this section of the state was deficient in calcareous matter, but from some experiments lately made on my farm by Mr. Briggs, one of the assistants of Dr. Rogers the geologist of this state, he has completely satisfied me of the actual existence of lime, with various combinations, and in situations where I had never before suspected it to be. With a vial of muriatic acid in hand, we carefully examined the whole chain of rocks cropping out of the river hills bordering on the bottom ; and frequently applying the acid to such rocks as he indicated, they would rapidly foam, or effervesce, showing to a certainty the actual presence of lime. In some places we found the rocks combining nearly equal parts of lime and sand ; and the same vein or ledge, on pursuing it horizontally, would evidently change its character to ferruginous, indicating thereby combinations of iron.

The very best specimen of calcareous earth we found, or that I believe our country produces, is on the bosom of some of our river hills. They are those red, naked barren-looking places generally spoken of here as "*buffalo stamps.*" There is one near my house, and on it much fine, pure, limestone gravel ; the red earth freely effervescing with acids, and apparently so highly calcareous as to produce no vegetation whatever.

I must believe that the discovery of this calcareous earth may be made of vast importance in the future improvement of our soil. Its application to our sandy land particularly, when in a sod of grass and previous to turning under for corn, would surely add greatly to its production. I shall, on the first proper occasion, try the effect on some of my fields, and report to you hereafter the result.

Further and more extended observations since Mr. Briggs left the neighborhood have enabled me to trace several ledges of tolerably good limestone, (combined with sand as usual), at the distance of two or three miles from the river. Finding such specimens thus located at different angles around us, I am now satisfied of the existence of sufficient calcareous matter in our soil for all the purposes of good husbandry and profitable farming.

It is the opinion of geologists, that the character of a soil is determined by the rocks that lie underneath it, the soil being formed by the disintegration or decay of those rocks. If such is the fact, water percolating through them will carry off carbonate of lime held in solution ; and that same cause thus operating for ages over the rocks, must have incorporated considerable calcareous matter in the soil. You will have observed, that under those ranges of rocks so common to our creek and river hills, you see the land is very frequently as rich as our best river bottoms ; and to what other cause than the one before mentioned can we attribute the fertility that is known to exist in that particular situation?

Our alluvial bottoms, formed originally by deposition from the river, and almost annually inundated, have naturally been manured by the deposite, containing more or less of every substance over which the water should happen to have passed before reaching them. In this way we can readily account for the unsurpassed fertility of the upper Kanawha bottoms. It has been the first receptacle for the wash from the limestone region above ; and the component parts of the soil formed by chemical combinations of the most fertilizing of all manures.

If we are fully satisfied of only a small part of calcareous matter present, we can enrich our soil to any desirable extent by the application of vegetable substances ; and in what other way can they be more readily obtained, than by sowing clover and other grasses? It will always be in your power to make a direct use of your clover sod, by turning it under, with such other materials as your care and attention may have enabled you to save for that purpose ; or you may pursue with your grass the system of grazing cattle, making them the principal auxiliaries in enriching your estate.

I had a good opportunity the last summer of comparing the relative merits and advantages which different principles of farming produced in various parts of this country ; and as the result of my observation has added to my previous conviction of the utility, profit and advantage arising from grazing, as well as the vast y increased

fertility and improvement of those farms on which it was judiciously practised, I will here state somewhat in detail such consequences as I observed growing out of each system.

My tour extended from the James river to the Potomac, in the Valley, and through a part of Loudoun county.

It is well known that nearly all the Valley of this state is highly calcareous, based on limestone rock cropping out in many instances so as to obstruct agricultural operations. To me, in some instances, it was matter of perfect astonishment, that with the materials of inexhaustible fertility lying in profusion around them, I observed some fields going to waste and profitless ruin, from the want of clover and other grasses sown upon them. I perceived that even there, where the land was certainly calcareous, if they failed to combine the vegetable matter, all their efforts at general improvement were given to the winds; as they had added nothing to stimulate into active use the fertilizing properties of the lime.

I saw, in various situations, huge mounds of calcareous tufa, or travertine. This is deposited from water holding carbonate of lime in solution, by means of carbonic acid. As the excess of the acid escapes, as it does generally at some fall or ripple, the lime is deposited in the form of an impure porous carbonate, frequently encrusting stones, leaves, and sometimes trees. Never, I believe, has the hand of Providence placed any other substance of such utility to agricultural purposes, more readily at the command of the farmer. It is easily calcined, and then used as lime; or may be readily ground like plaster, and applied in large quantities on clover sod previous to turning under. In no instance where it exists in such abundance could I learn that it was used for any purpose whatever.

I could wish, for the future welfare and future improvement of the spot of my nativity, that Mr. Ruffin, the editor of the Farmer's Register, would at some time extend his trips up into the Valley, and bring into active and general use this treasure, now neglected and unnoticed.

It is thus, that often the treasures of our country lie dormant and unknown, from our not having proper agricultural surveys to bring them to light, life, and usefulness.

I found on every estate, where due attention was paid to grazing, and alternating their crops, evident improvement, particularly when aided by the grazing of cattle, long considered there as almost indispensable to the perfect management of their lands. In Loudoun, through their cattle, wheat, clover, and plaster, an impulse has been given to good farming, unequalled, I believe, by any county in the state. I there saw with pleasure, lands that I well knew thirty years ago, then poor, exhausted, gullied, and worn out, now perfectly reclaimed, and covered with cattle and most luxuriant crops of grass. I was satisfied, by comparing their oldest grazing farms with those more recently converted into them, that it was to that system mainly they were indebted for their high state of fertility. The use of plaster first gave them clover, that created the necessity of buying stock to consume it; and the continued repetition of the use of both has now produced such consequences as evidently justify the wisdom of this practice. But little corn is raised; wheat and cattle are staples of the best managed farms. Their oldest pastures are now well combined with green-sward, indicating increased fertility. It enables them to compete successfully as graziers with any other part of the state, and sell annually upwards of twelve thousand cattle.

To that county I may justly appeal for full evidence of what may be realized by the use of clover and its concomitant advantages. We have seen her exhausted fields reclaimed and made productive, her people prosperous and increasing in wealth, number, and resources. Why should we not profit by her example? I have no doubt that we now possess a much finer natural soil than theirs, and containing more calcareous combinations, the converting agent of vegetable matter. Our rolling hills and alluvial bottoms present a noble field for continued improvement. They now invite the fostering care of good husbandry. Let us then take counsel from that experience of others which is before us. Let us pursue that course which will surely increase the fertility of our land, and carefully avoid such a suicidal policy as would allow any part of our land to remain uncovered with clover or other grasses.

In thus urging on you the propriety of sowing grass on all occasions as the first move in a course of regular improvements, I would remark that proper care and attention should always be given to other resources at your command as auxiliaries, to be applied when necessity and circumstances may indicate. Your cornstalks, straw, hay and barnyard manures have their appropriate place, and time of application, in a correct rotation of crops.

The weeds that annually spring up on every farm should be cut before they mature their seed. Nothing more exhausts your soil, and prevents the formation of a good sod.

I will here warn you to beware of the blue thistle and ox-eye, two of the most foul and noxious weeds I know. They have topped the Alleghany on their march to the west, and high waters in a short time will assuredly float their seed among us. Declare a war of extermination against them at sight. Care and attention given in time can prevent their spreading, and hold them in subjection; but if neglected they will take entire possession of whole fields, to the utter exclusion of every production. I have seen whole sections of the state so polluted with these weeds, as very materially to lessen the income and value of the land.

The last season has very generally proved unfavorable to the maturity of wheat. In the Valley and in Loudoun, I was informed, that the early spring gave indications of a most abundant crop. At harvest I found those promising appearances blasted, and universal destruction occasioned in that county by the rust.

Our crops this year have certainly excelled that fine wheat growing region. As I returned to the west, I observed a change commence at the North Mountain, and gradually improving to the Ohio.

Some experiments were made last year by Mr. McMullin, a member of our society, with a view of ascertaining the best period for seeding wheat. A part of his crop was sown on the first day of August, another part in September, and the balance in October. The product has

proved very different. The first sown entirely escaped the rust, the straw unusually bright and clear, the grain full and plump, equal in quality to any produced in our best seasons—second time of sowing succeeded next—and the last materially injured by rust. This trial, however, I do not believe entirely decisive, because the last peculiar season has had great influence on the final result. Further experiments ought to be made and reported. It appears to me that the time of sowing wheat should be regulated to avoid, if possible, the two greatest evils by which our crops are endangered. I mean the fly and winter killing. Very early sown wheat will get firmly rooted before winter, if it should escape the fly; on the contrary, late sown is full as liable to receive injury by freezing out.

I would look to the particular character of the soil to determine when is the correct time of seeding it, for heavy clay land is more likely to be thrown up than light sandy soil; sandy soil retaining less water. In comparing the several casualties attending our previous crop of wheat, I am induced to believe that the chances are most in favor of the early sown producing the best crop. Make your land rich, and the fly can do no injury compared to the risk you will hazard in delay, from rust and winter killing.

I expressed my sentiments so fully in my last communication on the growth and culture of the corn crop, that I will now say but little on that subject. I yet entertain the opinion that the best preparation that we can give to land, to produce the greatest yield, should be applied when it is in a grass sod, and previous to turning it over. Whatever efforts are then made to manure and enrich the soil, the benefits resulting therefrom will be immediate and direct. I consider that deep ploughing at the same time is essential, and almost of equal importance to secure a successful crop. In no other way can we guard more effectually against the withering influence of our dry seasons, than by thus creating a depth of mellow soil, which repels its effects by lessening evaporation.

The advantages resulting from the growth of the root crops are now justly appreciated by those who have given most attention to their culture. Rising in importance in every section of the country where they have been tried, they are there considered an indispensable crop to every well conducted system of husbandry. They have proved admirable food for cows. I saw in a Philadelphia paper a publication, stating that the best lot of winter butter ever offered in that market was then exhibited, and had been made entirely from the sugar beet. Several members of this society have cultivated these crops with great success. To their experience I will refer you for practical information in regard to this culture.

I would again recommend enclosing your wood land, and converting it to standing pastures, by cutting off the small timber, and then thickly seeding it all with grass. My own experience convinces me of the great benefit resulting from adopting such a course. Those pastures that I have heretofore made, improve under grazing, and certainly will repay the amount of labor expended on their formation. I am so satisfied with the experiment, that I shall continue to increase them until all my hill land is converted into profitable pastures. Other opinions, in aid and in confirmation of my own judgment, will induce me to persevere until its final accomplishment. A gentleman who had carefully examined our hill land, and the grass growing on it, expressed his admiration at the prospect, and stated his firm belief of its capacity to rival Kentucky in good grazing. I have great confidence in his intelligence and opinion on that subject, as he is himself an admirable grazier, and well acquainted with Kentucky.

There is nothing that gives more security, or adds a greater ornament to a farm than good fencing, when judiciously arranged. The great convenience which we now have of getting rail timber, or other materials, for its construction, should induce every farmer to make substantial enclosures. How often have we seen ill-will created, and the peace, quiet, and harmony of neighbors disturbed, from the want of such adequate fencing as would give security to their crops. Very few can bear with much patience trespasses daily committed on their property, without complaining; and yet it most frequently happens, that they alone are in fault, through their own negligence and bad management, for all the injury that they have received. The law, as it now exists, permits stock to run at large, and it is your first duty to yourself and your neighbor, to guard against their depredations, by making such adequate fences as will secure your crops.

I have sometimes observed, that through inattention and carelessness to the duties of good farming, briers have been permitted to grow up in fence corners, and not unfrequently to extend over whole fields. Such negligent conduct is justly reprehensible; for surely if our land is of any value to us, it is worth our attention and protection. Nothing is easier to keep under, or even to extirpate entirely from a field, than briers. Sow your land thickly in grass, tread it with stock, apply the scythe when required, and avoid ploughing until you have a perfect sod. To lighten up the soil by the plough is to increase their growth. Their destruction is only effected by binding with grass.

The exhibition of yesterday has satisfied me, that increased energy and activity has been already given to the productions of the country by the operations of this society. The fine stock shown was creditable to their owners. The root, grass, and grain crops as abundant and productive as the season would justify. But it is in the department of female ingenuity and taste, that we are delighted to find the principal sources of the interest and pleasure belonging to our exhibition; and to the ladies would I award the greatest praise, justly earned by their spirited exertions. The number, beauty, variety, and superior quality of all the articles presented by them for premiums, were objects of just admiration to all who saw them. We earnestly hope that they will continue their exertions, and we well know, that when aided by the ladies, our cause will prosper

———

ROTATION OF CROPS.

To the Editor of the Farmers' Register.

Much has been said and written on this subject, and not without cause; for of all the matters which necessarily engage the mind of the reflecting farmer, it would be difficult to suggest one more important. Besides the editor himself, many successful farmers and able writers have expressed their views in full on this subject throughout the whole series of the Farmers' Register; for example, Messrs. Carter, Selden, Wickham, Harrison, Roy, Tabb, Braxton and many others, whose names have only to be mentioned at once to arrest attention and give weight to the views advanced by them respectively. These gentlemen live, nearly all of them, in *grain-growing* districts of old Virginia, are good agriculturists, by which I mean that they not only make good crops, but also yearly improve their lands, and yet they advocate different systems of rotation of crops, varying in the number of years through which the rotation passes from two to six. Nay more, the same gentleman has at different times on the same land advocated different systems—and still been successful. How is this? Does it prove that rotation is a matter of no importance? Not at all. It only proves that different soils and different situations require different systems—that it would be the height of folly to make all soils and all crops bend to one uniform system—and that even under a bad system, good management and good cultivation may and will produce satisfactory results. Let it be remembered however that the converse of this proposition is not always true. A good system will not always counterbalance bad cultivation and bad management. While having an eye, and a close one too, to the most important, let not the farmer neglect the many smaller matters, which in the aggregate may not the less affect immediate results.

If so much has been written and ably written too, what need of more? perhaps the reader will ask. I readily answer, because the subject is important, and every *fact*, however apparently trifling, drawn from experience, connected with it, is important, and one or two facts I wish to communicate, besides wishing to draw information and advice from others.

In determining on every system of rotation, a few important points must be looked to. Is the principal business of the farm the raising of stock or growing of grain? If the latter, is the land best adapted to the growth of wheat or corn? Is the farm level or hilly? Does the farmer enjoy great facility of getting his products to market, or the reverse? And several other leading matters which will readily suggest themselves.

It is not my object to discuss at this time the best rotation for every possible variety of soil and circumstance, but to call attention to that which I consider best adapted to a grain-growing farm, situated on tide water, adapted better to the growth of corn, but capable of producing very good clover and wheat.

Such generally is my farm, but it is necessary to state that it is very rolling, and that there are 60 acres of land very stiff and totally unfit for producing corn. In fixing on my rotation, I set apart these 60 acres to be divided into two fields to be fallowed alternately for wheat, and to be kept in wheat and clover as long as they remain clear of blue-grass and other pests. The remainder of my farm I could not so readily determine on. When I received it, it had been cultivated for some years on the four-shift system of Arator, fallowing however to a very small extent each year. The portion of the field not fallowed, by lying out so long, became excessively foul with sassafras, locust, wire-grass, and innumerable pests of the vegetable kingdom, so that preparing it for the next corn crop was an Herculean task. I soon found that would not do; that most of my yearly labor was expended in conquering a growth of pests only to be again repeated when the land came again into cultivation. But what to do? There was the rub. I knew that my land, with my indifferent management and limited means of manuring, could never stand the scourging system pursued with such eminent success on the fine wheat soils of Westover and Shirley, and under the superior management of Messrs. Selden and Carter. I could not adopt the three-field rotation of corn, wheat and clover; because my land was so hilly, that a hoe crop every third year would soon cover it with washes and gullies. Besides, I was fully convinced of the great improvement to be derived from summer-fallowing, the importance of having some work of this kind for the horses to do at this otherwise idle season, and the great advantage of having one field ready when the 10th of October (my seed-time) came. I confess that having, as I mentioned above, 30 acres to fallow each year, I was about this time much tempted to yield to the arguments of Mr. Harrison, Mr. Tabb and Mr. Roy, to whose interesting communications I would refer the reader, but was prevented by the hilliness and rolling nature of my land. I have no sort of doubt that the system which they so ably recommend is the one best adapted to most of lower Virginia, which is generally level and better fitted for corn than for wheat culture. The consideration that corn is a very certain, and wheat a very uncertain crop, deservedly had much weight.

Being driven from the three and also from the four-field rotation, I next very naturally turned my attention to a five-field system. I was the more reconciled to this, because about this time I heard that Mr. Harrison was thinking of abandoning his favorite three-field for the four-field system, and that Messrs. Selden and Carter were meditating a change from their boasted four-field rotation to one of five fields. These gentlemen are our Cokes and Blackstones, in matters of agriculture, on lower James river, and I must be excused for adducing them as *authority* so often.

A five-field system was then the thing. The best arrangement for five fields of which I had heard was that pursued successfully by Mr. Wickham, viz., corn, wheat, clover, wheat, clover. But I learned from Mr. Harrison that under this arrangement my farm would become foul—one of the principal objects I had in view in abandoning my old system (Arator's four-field.) A second objection was that the clover, on the authority of Mr. Selden, would most likely fail after the fallow crop of wheat. A third and very serious one was that if the crop of clover preceding the corn was closely grazed it would be rendering the earth close and compact, which was much to be re-

gretted for corn, and would be bringing the three grain crops and one year of grazing all in close and rapid succession. On the other hand, not to graze would be to insure a fine crop of vegetable pests; they in turn furnishing a nest to breed, and a harbor to protect, an equal number of animal ones. I shall revert to this system; it has much to recommend it. "Rivanna," a writer in the 8th volume of the Farmers' Register, considers it the beau-ideal of a system of rotation. By the way, if his eye falls on these desultory remarks, will he inform us whether his opinion is the result of actual observation and experience, or a deduction from theoretical principles? Dr. Braxton too recommends it as highly improving after several years' experience.

At this juncture there appeared in the volume of the Register for 1839, several essays (I judged) by the editor, in which he discussed the manuring and cleansing of lands by their own growth, and the application of the principles of the rotation of crops. A suggestion there met with made me hope that I could adopt the four-field and fallow rotation, with all its great benefits, without any detriment to the land; which was, that by sowing peas broadcast amongst the corn at the time of laying it by, an excellent pea fallow might be had the same fall. Such a pea crop would not only be alternating the *kinds* of crop, but would be furnishing enriching matter to the land for its improvement. I tried it; but failed so completely on the first trial that I was never after induced to repeat it. Yet such practice is highly recommended, and Mr. Braxton, in his valuable article on rotation, in vol. viii., if I mistake not, says that he has practised sowing peas in this way, and with success. I also tried sowing buckwheat in the same way, but with no better result. All would not do. To the five-field rotation I was driven. Having thus unconditionally made up my mind to adopt five fields, I was anxious to adopt the plan most improving, and which also would yield most immediate profit. I adopted a system suggested in one of the above mentioned essays, viz.:

First year, corn.
Second do. peas, fallowed in fall for wheat.
Third do. wheat.
Fourth, do. clover.
Fifth do. wheat.

And wishing to derive every benefit, I also adopted the recommendation of sowing the corn field in rye in the fall; the rye to be turned under next spring while in flower for peas. I did not derive the slightest benefit from the rye. If the month of May happened to be dry, I found it very laborious ploughing the land in rye, even when other land did not appear very hard; and I soon became convinced that if any benefit did accrue to the land from the rye, it was not sufficient to remunerate me for expense of seed and ploughing. I have since seen, in one of Mr. Carter's papers, that he came to the same conclusion with regard to oats turned in for improvement, from an experiment actually made. I also substituted, when ill-supplied with seed-peas, buckwheat for the peas. But I never found any benefit from it. Nor ought it to have been expected. Both rye and buckwheat are narrow-leaved, fibrous-rooted, grain-producing plants, and no doubt must draw nearly as much from, as they can return to, the earth.

My rotation now stands—1st year corn, 2d peas, 3d wheat, 4th clover partially grazed, (late,) 5th wheat. About half of the corn land is put in oats and sown in clover, leaving only half for peas and wheat. That put in oats of course remains two years in clover, and, with the help of a standing pasture, supports the stock, till time to glean the wheat fields, both of which are grazed moderately. In fact I have come to the conclusion, that light or corn land, like mine, to improve *progressively*, must be grazed. There might be faster improvement, for a short time, without the hoof, but it would sooner cease to progress.

To my present plan there are strong objections, which I will briefly enumerate. 1st, the expense and labor of the additional ploughing for peas, when compared with the sowing of clover in the five-field rotation of Mr. Wickham. 2d, clover is not apt to succeed very well after the wheat on the pea fallow. Whether the peas render the land too porous, or whether the rank growth of wheat which succeeds a rank growth of peas smothers the clover, I am unable to say. A third objection is, that the oat field, being followed two years by clover, becomes very foul. And two years in clover are necessary to bring that portion into rotation with the other half of the field reserved for wheat. I select for the oats the most rolling portion of the corn field, which is thereby subjected to one ploughing less in the rotation than the remainder of the field, and if it becomes more foul, my idea was that it would be less apt to wash; and of the two, foulness or gullies, I greatly preferred the former. But even in this I have been disappointed, for by this arrangement, it will at once be seen that the land intended for oats lies throughout the winter without any vegetable cover, and of course in the worst state for the action of the rains. I believe that if I adopted the five-field system, marked below No. II, and followed the corn by wheat on all the rolling parts and by oats in all the level parts, the whole to be sown in clover and fallowed the following fall twelve months, that it would not only be better, for guarding against washing, but also it would be a more cleansing system, so far at any rate as the oat land is concerned.

I confess that I am now wavering between the two systems and have not yet come to a final determination. If any brother farmer can aid me in my quandary he will receive my warmest thanks. I cannot do with less than five fields; and the question is shall I adhere to my present five field and (pea and clover) fallow rotation, or shall I adopt Mr. Wickham's system of five-fields, two of which are in clover. To compare them better I will place them in juxtaposition.

I. Pea & clover fields.	*II. Two clover fields.*
1st year corn.	1. corn.
2d " half in peas, and half in oats.	2. half in wheat and half in oats.
3d " half in wheat & half in clover.	3. clover.
4th " clover.	4. wheat.
5th " wheat.	5. clover grazed.

I think both capital rotations, as free from objections as any rotation contained in 5 years or less time can be, but they still have their objections, some of which I have stated above with regard to each one. Here I would only ask a single question. Would as much wheat be made on the 2d as on the 1st plan? A reduction of the

profits of each to figures I am unable to give, never having tried one of them.

I am aware of a third scheme of a five-field rotation recommended and adopted by Mr. Carter. But in my humble judgment it is inferior to either of the above; and in this opinion I am supported by Mr. Braxton, and by a writer over the signature of R. in vol. viii.

In the above remarks, I have frequently called to my aid the authority of many of your ablest correspondents, and in doing so it is hoped that the opinions of none have been misrepresented. If otherwise, I hope to be set right; and cannot conclude without remarking that if this communication has no other merit, it has at least that of presenting in one view a long list of Virginia's noblest sons and benefactors. *Benefactors*, I say, for by regenerating her soil, they have done her more service, than the whole host of her politicans for the last forty years. N.

February, 1842.

ON THE FARMING OF THE REV. JESSE H. TURNER.

To the Editor of the Farmers' Register.

It is a sort of adage that there are "secrets in all professions." I believe, however, that there is an exception to this as there is to most general rules. The profession of farming is an exception. By common consent, the experience of every farmer is common property with his brother farmers, and it is generally conceded that every farmer has a right to call on others for such information as he wishes, without the fear of refusal. With these remarks I would take the liberty of making an appeal (and I hope not in vain) to my old friend, the Rev. Jesse H. Turner. In a recent visit to his farm I was delighted at the neatness, order, system and high state of fertility which he had effected in a few years. But that which most of all is to be admired and is the best test of good farming, is that he makes his farm very profitable. Now I hope Mr. Turner will excuse the call which I make upon him, and gratify me as well as do the public a service by giving a general detail of his system and management. I hope he will give us a series of essays embracing his *whole* system, rotations, corn-culture, grass-culture, manuring, fallow, &c.

W. J. Dupuy.

[We have, long ago as well as recently, made similar requests of Mr. Turner, and now heartily second this public call made on him by our correspondent. We know of no one whose practice has been more successful, or profitable, in his situation, of a farmer near enough to a city to use bought manure. Still, we think that he has so far missed one of the greatest means to aid and fix his other manurings of his fields, in neglecting to apply lime. Without this, or some other calcareous manure, on a naturally poor soil, all putrescent manures are but of transient effect, and are rapidly lost. Mr. Turner has made unquestionable and very large agricultural profits, by continually renewing large supplies of purchased putrescent manures, added to his own farm supply. But if he had made his soil calcareous, it would render the other manures permanent, and also make the crops better and more certain, than can be done by any possible amount of putrescent manure alone. While fully believing that both the enriching and the profits of Mr. Turner's farm have been very considerable and unusual, we must still also believe that there is yet wanting, in the use of lime, the "one thing needful," to render his improvements permanent, and his farming far more perfect and profitable.—Ed. F. R.]

THE FARMERS' REGISTER.

VOL. X. MARCH 31, 1842. No. 3.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

SANDY POINT ESTATE.—NO. V.

To the Editor of the Farmers' Register.

Sandy Point, 18*th February*, 1842.

The following communication will present a general summary of the farming operations, on this estate for the year 1841, (exclusive of those which may have been noted in former numbers,) and would have been forwarded to you ere now, had not a protracted indisposition and other causes induced delay.

The 1st of January, 1841, found us with a very considerable proportion of the corn crop of 1840 yet out in the field, being prevented from hauling off the land sown in wheat, by the continued wet weather, and consequent soft state of the ground; nor was all got in till the 15th of February, when the last loads were got up, all in good and safe condition.

Fallowing operations for the corn crop of this year (1841) were fully two-thirds executed prior to the 15th of December preceding, and it proved fortunate that we were so far in advance, for the unprecedented wet winter effectually put a stop to all such operations. Nor were we again able to resume fallowing earlier than the 22d of February. The general condition of the ground then being wet and heavy, we were only enabled to plough on drier portions of corn ground, and that intended for oats.

At intervals, during the last week of February and 1st day of March, 24 bushels of clover seed were sown amongst wheat; the ground in good condition for receiving the seed, which was sown without receiving either a subsequent harrowing or rolling, and has generally succeeded well. One gallon of seed was sown per acre, and from the apparent abundance of plants has proved to have been an abundant supply. Not more than 30 acres of the land thus sown in clover had been rendered calcareous by a preceding application of lime or marl. The larger proportion was sown on a neutral soil, a portion of which might be considered rich; but much the greater part of only medium quality as to fertility, and a few acres of a lighter soil, decidedly poor. On this latter the stand of plants, as was anticipated, is very sparse, on the other and larger portion of neutral soil, the general stand is pretty good, though greatly inferior to that sown on land of an exactly similar nature, and which had received the benefit of a dressing of either lime or marl, on which the plants are not only thickly set, but now present a luxuriant appearance.

Oat sowing was commenced on the 2d of March, but, in consequence of delays from frequent rains, was not completed until the 30th of the month. On corn ground of the preceding year there were sown 220 bushels, and 113 on a weed and clover fallow, intended for ploughing under at the proper season, as a preparatory green manuring for wheat. The result of this crop was extremely indifferent. Oats suffered from drought; straw was generally very short; and the grain was also indifferent—the whole being little short of an entire failure. The seed originally was not pure, being a mixture of the common and ruffle oats, not so from choice, but from carelessness in storing past seed, or by some other means allowing them to become mixed. The sowing of them in this mixed condition, for two or more years, resulted in both varieties becoming degenerate and unprofitable, so much so as to induce an entire change of seed, and that to the common in preference to the ruffle oat.

Fallowing of corn land was completed on the 2d of April, and even at that late season with difficulty; a wetter, or more harassing season for general farm operations I have never encountered. Planting of corn was begun on the drier and lighter portions of ground on the 27th of April, and, including some delays from rains, was finished on the fourth of May. The extent of ground planted, as stated in a former communication, being about 603 acres. The whole had been carefully fallowed by three-horse ploughs. The larger proportion of the several fields being of good soil, the growth of clover and weeds was generally heavy. About 130 acres of the whole had received a dressing of lime or marl, the greater proportion of the latter immediately before planting. A small portion had been limed some years previous. After fallowing, the whole was well and finely harrowed, and where judged necessary was re-fallowed, and again harrowed. All being thus considered in good condition for receiving the seed, so far as being in good tilth could be beneficial. Where not liable to be injured by surface or other water, the corn was planted in checks, and cultivated in both ways; but where liable to become wet, particularly in stiffer bottoms, or sufficiently sloping to be washed by heavy rains, drill planting was adopted. Markers previously passed over the fields, laying off or marking the rows; the seed furrows were then opened by one-horse mould-board ploughs, the planters following after at a convenient distance, dropping the corn and slightly covering it with the foot, and heavy harrows following after and finishing the operation. By this mode, in good weather and free from interruption, our average planting per day is equal to 150 acres, and the fields are left in neat and good condition. The harrowing of the land after corn planting I consider a very desirable object; the surface of the ground is left in the cleanest and best possible condition, and if properly executed is little inferior to a course of ploughing; and it also proves the best defence against the attacks of crows that I have yet known. A small portion of bottom land was left without the harrow passing over after planting. On this spot the crows picked up nearly every hill, but where harrowed very few hills were missing from this cause. With the exception of some of the stiffer bottoms of the best portion of the fields the general crop started well. On about 125 acres the cut-worm unfortunately soon commenced its ravages, and on which it was with the greatest possible difficulty that corn could at all be got to stand. Much of this

land was, subsequent to its original and also first replanting, twice ploughed up entirely, and replanted; and then recourse had to be had to setting out plants from other portions of the fields. After this pest had in some measure desisted from its inroads, the bud-worm commenced operations, and likewise did no little damage; so much so that on the 22d of July, when the culture of the corn crop terminated, these portions of the fields did not afford the prospect of yielding any crop. Rains occurring early in August did much to give it a start, when it improved much more rapidly than I could have anticipated. The results, however, though better than expected, were little if any over one third of a crop, and that from the richest portions of the fields, with this exception, a heavy one. It must be admitted, it is considered that the general return will prove a fair average crop, but which cannot as yet be accurately ascertained. The course of culture pursued in this crop of corn was first throwing a furrow from each side of the corn with one-horse mould-board ploughs, and breaking the balks with trowel hoes. The second and cross ploughing was altogether with trowel hoes, the small, or as it is here designated the X trowel hoes, going next to the corn. Weeding hoes following after this ploughing as speedily as possible. Corn, with the exception of ditch banks and rich headlands, thinned to one stalk to a hill. The ploughs having finished the second ploughing, one-horse mould-board ploughs again run on each side of the corn, throwing the furrow-slice to the plants, the trowel hoes again in the balks. This course also finished, the whole is again gone over with the trowel hoes—seldom completed before wheat harvest interrupts; after which all grassy and foul spots receive another stirring with trowel hoes, followed also by the weeding hoes. Thus the larger proportion of the crop received five ploughings, performed as carefully as possible; and when laid by, the fields were in clean and good condition.

On the 5th of June one half of the barrel of poudrette which you kindly presented for experiment was applied immediately after the first hoeing (received too late for an earlier application) to a portion of the corn-field, where no marl or lime had been applied, selecting each alternate two rows of fifty hills each. A portion of these rows had a quarter of a pint of poudrette applied to each hill, and another portion had half a pint applied in a similar manner; and on June 15th, the remaining half of the barrel was applied on a portion of the field recently marled, selecting each alternate two rows as above, giving to each hill half a pint; and after careful observation throughout the season, I could not discover that any benefit resulted from the application in either case. Was the application properly made?

Very little of the blade fodder was pulled from this crop of corn, probably not more than 12,000 lbs., having been able, at the proper season, to cure a considerable portion of good clover hay, which, with the aid of cut and salted shucks for our horses and mules during the long winter nights, and on which they do well, will be sufficient for our consumption. Top fodder was cut from off little more than one third of the crop at a season sufficiently advanced not seriously to injure the corn.

On the 14th and 15th of June, 68 bushels of black-eyed peas were sown on a principally weed fallow; covering ploughed under of good growth generally, and in some places heavy. These were sown broadcast, and covered by one-horse ploughs, intended as a preparatory green manuring for wheat. The subsequent growth of peas proved to be good, causing considerable difficulty in ploughing them under. The results of this mode of manuring on the now growing wheat crop are looked forward to with considerable interest. On the 22d and some following days of July, a crop of oats on adjoining land was also ploughed under as a preparatory manuring for wheat. Crop of oats, unless on headlands of ditch margins, very indifferent; the second or volunteer growth, however, proved excellent, and was again ploughed under at the time of sowing the wheat. The soil on which both oats and peas were thus sown and treated was uniform; and to a portion of both, side by side, marl was applied in the month of September, a favorable opportunity will thus be presented of testing the comparative value of oats and peas as a green manuring.

Fallowing clover lay for wheat was begun on the 25th of July, and finished on the 20th of September, amounting in all, pea and oat fallow inclusive, to as nearly as can be judged not less than 525 acres. The whole performed with three-horse ploughs. On some portions of the fields thus fallowed occasional difficulties were experienced from the ground becoming hard and dry; but not to any injurious extent. The whole having been performed generally well, and being carefully levelled by heavy harrows, was left in good condition for receiving the seed; sowing of which was commenced on fallowed land on the 1st of October. Rain occurred on the evening of the 2d, and but slight progress was made until the 6th, when weather and ground both became more favorable for this important operation. Another delay occurred from the same cause from the 10th to the 14th, from which time the weather continued remarkably favorable for wheat sowing, until its completion on the 8th of November. On fallowed land there was sown 918¾ bushels of red or purple straw wheat, and on corn land 68 bushels of purple straw, 553¼ bushels of white Turkey, and 5 bushels of rock wheat, the whole being equal to 1545 bushels. All of the wheat was covered with two-horse mould-board ploughs, both on fallow and corn land. The heavy growth of grass on much of the latter rendered ploughing difficult and tedious. Heavy harrows followed once or oftener, and these again by hand-hoes. Water furrows were carefully opened, and the whole left in as good condition for the wheat as could be obtained. The time occupied in sowing and covering was equal to 26 days, or an average per day of 59$\frac{9}{26}$ bushels. The drought which prevailed until the middle of November caused the late sown wheat to vegetate slowly in many places; and had also an evident unfavorable tendency on the earliest sown and most forward wheat, causing much of it to assume a yellow or rather red appearance. So far as could be observed there was no fall attack of the Hessian fly. Up to this date, the unusually mild weather which has prevailed during this winter has caused young wheat to be generally very forward, particularly on fallowed land. I have never

before seen it look better in the month of April; and from this cause I greatly fear that a succeeding season of severe frost might have on it a most injurious if not ruinous tendency. Wheat sown on corn land is much less forward, generally however presenting an appearance not unpromising.

Of putrescent manures there were during the season, chiefly in the early spring months, 2599 loads hauled out: 245 loads of the finest or most rotted manure were applied on corn land in the spring; the residue mostly cow-pen and stable manure, only partially decomposed, was applied as a top-dressing on clover intended for wheat fallow. Every season's practice of this mode of application strengthens my opinion of its being the best and most profitable. The average quantity applied to an acre was 18 loads; each load such as is usually hauled out by six oxen on large carts.

Of calcareous manures there were 41,959 bushels of marl applied during the year. One-third of that quantity was applied in the spring previous to planting corn; the other two-thirds at intervals during the summer and fall months, on clover, pea and oat fallows, intended for wheat; the average quantity per acre being 170 bushels of marl containing 60 per cent. of lime. In all about 246 acres have been marled during the year, in addition to which 350 hogsheads of shells were burned in the spring and applied to land afterwards planted in corn, at the rate of from 90 to 120 bushels of lime per acre. A 20-acre lot had one half of it a dressing of lime at the rate of 120 bushels per acre, and the other half a dressing of marl at the rate of 200 bushels per acre, of same quality as above stated. A single corn row formed the dividing line between the two applications. The soil was of uniform texture and quality. The progress of the growth of the corn on both was narrowly watched during the season; little if any difference could be discovered. The crop on both was good, and if any difference did exist, I would say that it was in favor of the marl. Other individuals who had seen the crop expressed the same opinion. The entire 20 acres on which these applications were made are now in wheat, which crop may perhaps more directly test the relative value of the two applications.

In former communications I have noticed the happy effects which had regularly attended each application of lime or marl on this estate, and will now only observe farther, that time and more extensive applications strengthen the favorable opinions heretofore expressed.

The end of the year again found us with a considerable portion of corn still exposed in the fields sown in wheat. Not less than 525 to 550 acres of land have been fallowed towards crops of 1842, of chiefly clover and weed lay; and altogether operations are generally in a favorable state of forwardness, of which and their results more may be said in a subsequent communication.

A. Nicol.

THE CUT WORM.

From the American Farmer.

Mr. Editor—This is the popular name of a grub or worm, very destructive to corn, cabbage plants, potatoes, clover, &c. I have in vain searched through all the volumes of the "American Farmer," and other agricultural journals for a history of this insect. It has by some been intimated that a *black bug*, about an inch in length, of a quick and lively motion, was the parent of the cut-worm; but nothing like a rational history of its changes and habits has ever been given, so far as I have been able to ascertain. A very slight knowledge of entomology would be sufficient to convince any one that a "*black bug*" would not be the parent of a larva of the caterpillar kind, such as is the cut-worm. We are then to seek among the genus papilla or phalæna for its parent.

It is somewhat remarkable that the history of an insect so destructive to the principal crop of the farmer as is the cut-worm should be so shrouded in darkness or veiled in obscurity. Having suffered myself, and having long witnessed the sufferings of others, by the ravages of this destructive insect, I have for some years past made its history a subject of study and observation; and if I shall be so fortunate as to cast such light upon it as shall be useful to the agricultural community, for which I have a high regard, I shall consider myself amply rewarded.

In the year 1838, I had a short conversation with E. P. Roberts, esq., then editor of the "Farmer and Gardener," on this subject, and informed him that I was prosecuting some inquiries on the history of the cut-worm; at his request I promised him, when they were completed, to communicate them for that journal. Until last year they were not satisfactorily accomplished. On the 20th of July, 1841, I took from the root of a cabbage plant a full grown cut-worm, and put it into a glass jar with a little fresh earth, so that I might observe the changes it underwent. On the 30th it had become a chrysalis of a brown mahogany color, and on the 15th of August it underwent the last metamorphosis and become a moth, of a grayish hue, and of about one inch in length. These operations and changes were carefully noted in my farming and gardening diary, from which the above extract is made.

Being then possessed of the parent moth, I was enabled to fix on the order, genus and species of the insect; which are the following:

Phalæna—*moth*, of the order lepidoptera; flight nocturnal of the assortment noctuæ, wings incumbent, antennæ setaceous, of a grayish color, clouded and variegated, about one inch in length. It changes to a chrysalis in July, and the moth appears in August. It lays concealed in the shade of green herbage in the day time, devotes a few nights to love and sexual embraces, deposites its ova on the stems of green and growing plants near the roots; when, having performed these offices appointed by nature for the propagation of its progeny—it dies. The eggs hatch in a few days, the young brood commence their ravages on the green clover and attain about half their growth the same season, and lie buried at the root in a torpid state during winter. As the warmth of spring reanimates them, they become ready for

the corn crop, or the first green-plant that is presented to their gluttonous appetite.

It is entirely gratuitous to say that fall or winter ploughing will destroy them. I have found a cut-worm, nearly full grown, early in March, at the root of ripple grass (plantago.) After the extract, which I shall presently make from good authority, it is to be hoped that the destruction of the cut-worm will never again be mentioned as an apology for the pernicious practice of fall or winter ploughing—a practice tending equally to impoverish the soil with that of leaving it exposed, naked, to the scorching rays of a vertical sun.

In the 3d vol. of the old American Farmer, page 94, will be found the result of an experiment by Dabney Minor. He had a field of 110 acres of heavy clover stubble, 95 of which he had ploughed with two yoke of oxen to a plough in the fall of 1820. Ten of the 15 he had listed the next spring. Five he left standing in clover. The whole field thus prepared, with the exception of the five acres in clover, was planted in corn about the middle of April. "The worms commenced their depredations with the coming up of the corn. A large portion of the corn on that part of the field ploughed in the fall has been destroyed, and the remainder so crippled as to render it doubtful whether it will recover. The corn in the ten acres of the balk land, together with the clover in the balks, has been destroyed root and branch, and the five acres of clover adjoining have shared the same fate. I have never seen an instance of so entire and complete destruction. I have on this day, May 22d, reploughed and replanted the whole piece, with however but little hope of succeeding in a crop from it, for the worms are as numerous as ever." After this, let no one advocate fall or winter ploughing—*to kill the cut-worm!*

The only method to prevent this scourge is to turn under the clover crop early in August, before the eggs are deposited; and if this were done the *second* year after the clover is sown, it would be the better method, as well for this purpose as to prevent the blue grass from getting too much ahead. The rotation of crops should be changed, so as to let corn follow the wheat crop.

A knowledge of the history and habits of insects is useful to the farmer, that he may be the better enabled to counteract their pernicious influence. Next to the Hessian fly, the cut-worm is the most destructive to the growing crops. When clover stands three years they must destroy more than half the crop of the third year; but as this does not come so immediately under his cognizance, it is overlooked by the farmer.

The flight of the cut-worm moths is nocturnal, and they are attracted by fire. By kindling fires, a few nights in August, in and about clover fields, great numbers may be thus destroyed; and it may be observed, that for every moth destroyed at that time we prevent the probable increase of some hundreds of their progeny.

Last fall I spread on a clover field, intended for corn next spring, about 20 bushels of slacked lime to the acre, in the full belief that it will destroy the cut-worm; if I should be disappointed in this expectation, it will not be labor lost, as the land will be improved by the lime sufficiently to pay the expense.

The corn crop is so important to the farmer that he should not spare any reasonable exertion to ensure a full one. Replanted corn never comes to much, and it is not only a loss of time but perplexing to have our crop thus mutilated.

The rotation that appears most likely to succeed is the following—wheat, corn, oats, wheat, clover, clover. This will bring two fields each in wheat, one in corn, one in oats, and two in clover. This would serve for the six-field system. For the five field the following: wheat, corn, wheat, clover, clover. Either, by letting the corn-crop follow wheat, will be found a sure protection from the cut-worm, without fall ploughing. It is the clover which serves as a harbor and nursery for the cut-worm, as well as other insects; and as before observed, it should not be permitted to remain longer than two years. W. L. Horton.

Wood Lawn, Feb. 16, 1842.

REMARKS AND INQUIRIES ON MANURES.

To the Editor of the Farmers' Register.

I have just read, in your January number, an elaborate "essay on the making, the preserving, and the applying of manures." This is evidently from the pen of a sensible writer; but to farmers, who like myself are interested in acquiring practical agricultural information, it is desirable to know how far the writer's theory has been sustained by his practice. For my own instruction, then, I beg leave respectfully to inquire of him as to portions of the system he recommends:—

First, what is the number of his horned cattle; what number of acres he annually manures by cow-penning, (commonly so called,) and whether an equal degree of fertility is imparted to the land by this mode as by manuring from the stables and farm-pen in the customary manner?

Second, as to hogs. Can farmers generally afford to keep them up in the way described by the writer, and do they thrive through our long, hot and dry summers in that state of confinement? What amount of labor is necessary to collect the materials for them to work up into manure, and what is the comparative value of that manure, mixed, as it must be, with such immense proportions of mud, dirt and litter? What will a farmer's pork cost him, raised in this way, out of the immediate vicinity of a market?

In my county, reapers and mowers are worth one dollar per day. At this rate what will it cost, per acre, to cut down the weeds, &c., for litter, as recommended; and is not this practice injurious to the land from which they are taken?

The writer of the essay is, I take it for granted, an amateur farmer, and consequently he will not be offended by these questions, which have been suggested to my mind on reading it. They are put in a spirit of perfect respect for the talents and motives of the author.

Feb. 21, 1842. A Young Farmer.

TO KILL LICE ON COWS, HORSES OR HOGS.

From the Central New York Farmer.

Take the water in which potatoes have been boiled, rub it all over the skin. The lice will be dead within two hours, and never will multiply again. I have used ten kinds of the strongest

poison to kill lice all with effect, but none so perfect as this. M. T.

Ellisburg, Jefferson co., Dec. 30, 1841.

OF THE IMPROVEMENT OF RACES.

From Lindley's Horticulture.

What has been stated in the preceding chapter, concerning the preservation of the races of domesticated plants, is in some measure applicable to their improvement, because the very means employed to preserve those peculiarities of habit which render them valuable, will, from time to time, be the cause of still more valuable qualities making their appearance. There are, however, other points of great importance on which the gardener has dependence.

A fixed improvement in the quality of the produce of a plant can only be obtained in one of two ways; either *directly*, by accidental variations in itself, or *indirectly*, by the process of muling.

Direct alterations in the quality of seedling plants often occur from no apparent cause, just as those accidental changes, called "sports," in the color or form of the leaves, flowers, or fruit, of one single branch of a tree, occasionally break out, we know not why. Of these things, physiology can give no account; but it is known that, when such sports appear, they indicate a permanent constitutional change in the action of the limb thus affected, which changes may be sometimes perpetuated by seed, and always by propagation of the limb itself, when propagation is practicable. It is in this way that many of our fruits have probably, and several of the Chinese chrysanthemums have certainly, been obtained. It was apparently thus that the nectarine emanated from the peach. It is possible that many new forms of shrubs might be procured by keeping these facts in view, and that climbers might be deprived of their climbing habits; for it is known that the handsome evergreen bush called the tree ivy, which grows erect, with scarcely the least tendency to climb, has been procured by propagating the fruit-bearing branches of trees of considerable age.

But we are by no means destitute of the power of procuring, with considerable certainty, improved varieties, by an application to practice of physiological principles. In the last chapter has been shown the importance of securing the production of seed by plants in the most healthy state possible, because a robust parent is likely to afford a progeny of similar habits to itself. In annuals, however, this is apparently restrained within narrower limits than in woody plants, from the great difficulty of fixing a new peculiarity in the former, and the facility with which it may be effected in the latter case, by means of buds, cuttings, grafts, and similar modes of propagation. The great object of the scientific gardener who desires to improve the varieties of plants upon principle will be, then, by artificial means, to bring the parent from which seed is to be saved as near as possible to that state at which he desires the seedling to arrive.

It is well known that the abstraction of fruit and flowers augments the vigor of the branches, or of the parts connected with them, and that the removal from the former of any part which takes up a portion of the food employed in the support of the flowers increases their efficiency. Thus those varieties of the potato, which will neither flower nor fruit otherwise, may be made to do both by stopping the developement of tubers; and, on the other hand, the size and weight of the tubers themselves are increased by preventing the formation of flowers and fruit. The course, then, to take, in obtaining the largest possible tubers in a new variety of the potato, would be, in the first place, to effect that end temporarily, but during several successive seasons, by abstracting all the flowers and fruit, and by such other means as may suggest themselves; and then to obtain the most perfect seed possible by a destruction of the tubers during the season when seed is finally to be saved. Mr. Knight found, in raising new varieties of the peach, that, when one stone contained two seeds, the plants these afforded were inferior to others. The largest seeds, obtained from the finest fruit, and from that which ripens most perfectly and most early, should always be selected (*Hort. Trans.*, i. 39); and, in his incessant efforts to obtain new varieties of fruit of other genera, he had reason to conclude that the trees, from blossoms and seeds of which it is proposed to propagate, should have grown at least two years in mould of the best quality; that during that period they should not be allowed to exhaust themselves by bearing any considerable crop of fruit; and that the wood of the preceding year should be thoroughly ripened (by artificial heat when necessary) at an early period in the autumn; and, if early maturity in the fruit of the new seedling plant is required, that the fruit, within which the seed grows, should be made to acquire maturity within as short a period as is consistent with its attaining its full size and perfect flavor. Those qualities ought also to be sought in the parent fruits, which are desired in the offspring; and he found that the most perfect and vigorous progeny was obtained, of plants as of animals, when the male and female parent were not closely related to each other. (See the *Horticultural Transactions*, i. 165.)

There are no processes known to the cultivator so efficacious in producing new varieties as that adverted to in the last paragraph, that is to say, muling or cross breeding; and it is to these operations, more than to any thing else, that we owe the beauty and excellence of most of our garden productions; more, however, I think, to cross breeding than to muling. It was entirely by the first of these processes that have been so greatly multiplied and improved our fruits for the dessert, and the gay flowers that adorn our gardens. The pelargonium, the calceolaria, the dahlia, the verbena, and a thousand others—what would they be but simple wild flowers, without the power of man exercised in this way? "To the cultivators of ornamental plants," says Mr. Herbert,* "the facility of raising hybrid varieties affords an endless source of interest and amusement. He sees in the several species of

---

* See much the most valuable and practical account of cross breeding and muling which has been yet published in regard to horticulture, in the *Amaryllidaceæ* of the Hon. and Rev. W. Herbert, p. 335, et seq.

each genus that he possesses the materials with which he must work, and he considers in what manner he can blend them to the best advantage, looking to the several gifts in which each excels, whether of hardiness to endure our seasons, of brilliancy in its colors, of delicacy in its markings, of fragrance or stature, or profusion of blossom; and he may anticipate, with tolerable accuracy, the probable aspect of the intermediate plant which he is permitted to create; for that term may be figuratively applied to the introduction into the world of a natural form which has probably never before existed in it. In constitution the mixed offspring appears to partake of the habits of both parents; that is to say, it will be less hardy than the one of its parents which bears the greatest exposure, and not so delicate as the other; but, if one of the parents is quite hardy, and the other not quite able to support our winters, the probability is, that the offspring will support them, though it may suffer from a very unusual depression of the thermometer, or excess of moisture, which would not destroy its hardier parent."

In the many successful attempts made by Mr. Knight to improve the quality of fruit trees by raising new varieties, his method was to obtain crossbreds by fertilizing the stigma of one variety of known habits with the pollen of another also of known habits. But, in doing this, his experiments were not conducted at random, and without due consideration; on the contrary, we learn from himself that he was very careful in selecting the parents from which his crossbreds were obtained. He found that the general opinion, that the offspring of crossbred plants as well as crossbred animals usually presents great irregularity of character, is unfounded; and that if a male of permanent habits, and of course not crossbred, be selected, that will completely overrule the disposition to sport, "the permanent character always controlling and prevailing over the variable." He tells us that he usually propagated from the seeds of such varieties as are sufficiently hardy to bear and ripen their fruit, even in unfavorable seasons and situations, without the protection of a wall, because, in many experiments made with a view to ascertaining the comparative influence of the male and female on their offspring, he had observed in fruits, with few exceptions, a strong prevalence of the constitution and habits of the female parent. Unfortunately, however, this is precisely the reverse of the result at which Mr. Herbert has arrived in the very great number of experiments performed by himself on that subject, he believing that the male parent generally influences the character of the foliage, and the female that of the flowers (*Amaryllidaceæ*, p. 348, 377); and although it does appear to me that, in the majority of cases, Mr. Herbert's opinion is the more correct of the two, yet I fear there is too little certainty in the results of hybridizing to justify the establishment of any axiom upon the subject.

This power of muling, properly so called, is confined within very narrow limits, and can hardly be said to exist at all between species of different genera, unless under that name are comprehended some of the spurious creations of inconsiderate botanists. There are, indeed, many cases of species very closely allied to each other which it is either impossible to mule, or so difficult that no one has yet succeeded in effecting it. Mr. Knight never could make the Morello breed with the common cherry. I have in vain endeavored to mule the gooseberry and currant, and we do not possess any garden production known to have been produced between the apple and the pear, or the blackberry and the raspberry, any of which might have been expected to intermix. As to mules obtained between plants of distinct genera, we have, no doubt, upon record, some experiments said to have been performed successfully in crossing a thorn-apple with tobacco, the pea with the bean, the cabbage with the horse-radish, and so on; but Mr. Herbert regards these cases, and I think with great reason, as apocryphal, and not to be relied on; the fact being, as he truly states, "that in this country, where the passion for horticulture is great, and the attempts to produce hybrid intermixtures have been very extensive during the last fifteen years, not one truly bigeneric mule has been seen."

On the other hand, cross breeding will take place quite as readily among plants as among animals, and it is difficult to estimate the alteration which this process has really produced, although unperceived by us, in the amelioration and alteration of long-cultivated plants. We cannot reasonably doubt that a process so simple as that of dusting the stigma of one plant with the pollen of another, which must be continually happening in our gardens, either through the agency of insects or the currents in the air, and which, where it takes place between two varieties allied to each other, must necessarily produce a cross,—we cannot suppose, I say, that this occurs in our crowded gardens and orchards at that time only when we perform it artificially.

The operation itself, although so simple, consisting in nothing more than applying the pollen of one plant to the stigma of another, nevertheless requires to be guarded by some precautions. In the first place, it is requisite that the flower whose stigma is to be fertilized should be deprived of its own anthers before they burst, otherwise the stigma will be self-impregnated, and although superfœtation is not, by any means, impossible, yet it is not very likely to occur. Then, again, the application of the stranger pollen should be made at the time when the stigma is covered with its natural mucus; if not, the pollen will not act, either in consequence of the necessary lubrification of itself being withheld, from the stigma being too young, or because the stigma, from age, has lost its power of receiving the action of the pollen. Neither should the stigma be in any way injured after fertilization has apparently taken place. The art of fertilization consists in the emission, by the pollen, of certain tubes of miscroscopical tenuity, which pass down the style, and eventually reach the young seed, with which they come in contact; and, unless this contact takes place, fertilization misses. Now the transmission of the pollen tubes from the stigma to the ovule, through the solid style, is often very slow, sometimes occupying as much as a month or six weeks, as in the mistletoe.

Those who occupy themselves in attempts at improving the quality of cultivated plants should be aware of this: namely, that the real quality of either the fruit or the flower of a seedling cannot be ascertained when they are first produced; for it is only as plants advance in age that the secre-

tions necessary for the perfect production of either the one or the other are elaborated. Of this fact, the first produce of the black eagle cherry tree afforded a striking example. A part of it was sent, with other cherries, to the Horticultural Society; and it was then, in the fruit committee, pronounced good for nothing. It was so bad, that Mr. Knight, who raised it, would most certainly have taken off the head of the tree and employed its stem as a stock, but that it had been called the property of one of his children, who sowed the seed which produced it, and who felt very anxious for its preservation. It has now become one of the richest and finest fruits of its species which we possess.

It may be expected that some mention should here be made of double flowers, and of the manner in which they are to be obtained. But I confess myself unable to discover, either in the writings of physiologists, or in the experience of gardeners, or in the nature of plants themselves, any sufficient clue to an explanation of the causes to which their origin may be ascribed. There are, however, several facts apparently connected with the subject, which deserve mention.

A double flower, properly so called,* is one in which the natural production of stamens or pistils is exchanged for petals, or in which the number of the latter is augmented without any disturbance of the former; in other words, it is a case of the loss, on the part of a plant, of the power necessary to develope its leaves in the state of sexual organs. But what causes that loss of power we do not know. It can hardly be a want of sufficient food in the soil; for double flowers (the Narcissus, for instance) become single in very poor soil. On the other hand, it can scarcely be excessive vigor; for no one has ever yet obtained a double flower by promoting the health or energy of a species. When plants are excessively stimulated by unusually warm damp weather at the period of flowering, their flowers in such cases sometimes became monstrous: but the effect of this is to lengthen their axis of growth, and to form true leaves instead of floral organs, just the reverse of what occurs in a truly double flower; the varieties of rosa Gallica often exhibit this kind of change. In damp cloudy summers, some flowers assume the appearance of being double, by the change of their sexual organs into small green leaves, as occurred very generally to Potentilla nepalensis in the summer of 1839, but there was, at the same time, scarcely a trace of any tendency, on the part of those leaves, to assume the color or texture of petals.

There is, evidently, a greater tendency in some flowers to become double than in others, and especially in those having great numbers of stamens or pistils. All our favorite double flowers, hepaticas, pæonies, camellias, anemones, roses, cherries, plums, ranunculuses, belong to this class; and, in proportion as the natural number of stamens diminishes, so do both the disposition to become double, and the beauty of the flowers when altered. The pink and carnation with ten stamens are the handsomest race next to those just mentioned; while the hyacinth, the tulip, the stock, and the wallflower with six stamens, and the auricula and polyanthus with five, form altogether an inferior race, if symmetry of form, and regularity of arrangement in the parts of the flower, are regarded as beauties of the highest order. If the mere circumstance of a plant having but a small number of stamens be a bar to its beauty when made double, how much greater an obstacle to it must be the natural production of unsymmetrical flowers. This occurs in the snap-dragon, which, with a five-lobed corolla, has but four stamens; and the consequence is, that, when it becomes double, the flower is a confused crowd of crumpled petals issuing from the original corolla.

I have heard of attempts to produce double flowers by artificial processes, but I never heard of the smallest success attending such cases, unless the tendency to their production had already manifested itself naturally; as in the stock, which will frequently become single from having been double, in which case its original double character may be recovered. A mode of effecting this has been described by Mr. James Munro (*Gard. Mag.*, xiv. 121). Having a number of single scarlet ten-week stocks, he deprived them of all their flowers as soon as he found that five or six seed-vessels were formed upon each spike, by which means he compelled all the nutritive matter that would have been expended upon the whole flower-spike and its numerous seed-vessels to be concentrated in the small number which he left; and the result, he says, was, that from the seed thus saved he had more than 400 double stocks in one small bed.

There can, I think, be no doubt that, if any original change to a double flower can possibly be effected by art, it will be more likely to occur with respect to those species which have an indefinite number of stamens, where the tendency to this monstrosity already exists. It is not many years since the chryseis (Eschscholtzia) Californica, a polyandrous plant, was introduced to our gardens; and I, at one time, made some attempts to render it double, conceiving it a good subject for experiment on that account, but I had no success; it has, however, accidentally become semi-double in Mrs. Marryat's garden, at Wimbledon; and I entertain no doubt that seed skilfully saved from that plant would present its flowers in a still more double condition.

* What is called a double dahlia is misnamed; and so are all so-called double composite flowers. The appearance of doubling is caused in these plants by a mere alteration of the florets of their disk into the form of florets of the ray; a very different thing from double flowers.

CLOVER AND TIMOTHY--MANURE.

From the Union (Ill.) Agriculturist.

* * * Whilst writing permit me to say, that my experience in raising grass (having cultivated as much as any in this county) amounts to this—clover and timothy mixed will yield one third more hay in lbs. than timothy alone, and more than clover alone, and will stand a drought much better.

Further—Land that is well manured produces double the crop of that which is not. I have tested it in the same field. Rushville prairie appears as rich as any land I have seen in the state, yet *one* load of manure will do as much good as on any land I have ever noticed, however poor. Yours, J. D. MANLOVE.

Rushville, Dec. 21, 1841.

ON GUANO.

(Continued from page 58.)

Of the economical or money value of guano to the English agriculturist.—We come now to consider perhaps the most important question of all, namely, the probable economical value of guano to the English agriculturist.

It may by most persons be considered impossible to arrive at any satisfactory conclusions in regard to this point except by actual experiment—by the trial, that is, of its *precise* effects on different crops and in different soils. This is no doubt the most certain and unexceptionable method of determining its value—but this method requires time, and the concurrence of many individuals. Until these trials are actually made, therefore, we are entitled to inquire of theory how far it can assist us in forming an idea of the absolute money value of this new manure, and we shall be justified in allowing ourselves to be in some measure guided by the answer which theory may give.

I.—Let me first introduce the partial results already arrived at by practical men.

1. Mr. Skirving writes me thus:—"With regard to the relative cost of guano and farm-yard manure, allowing guano to cost 25*s.* per cwt., which I believe is the price at present, it would cost no more to supply 8 cwt. to the acre than 20 tons of manure would; for in this neighborhood in spring-time good horse and cow dung is never under 10*s.* or 12*s.* per ton, besides the heavy carriage and extra expense of application, which on some land would make a great difference."

2. In connexion with his experiment on turnips, above detailed, Mr. Pusey remarks that, although it is impossible to form an opinion from a single experiment, he thinks a farmer who could afford to dress with 20 bushels of bones per acre, at 3*s.* a bushel, might find the guano answer at 20*s.* per cwt.

These two opinions, formed from imperfect or incomplete experiments, are valuable so far as they go; but they can neither as yet be considered a safe guide to the farmer, as to what he may venture to pay for this manure,—nor to the merchant, as to what he may venture to ask for his commodity.

II. But for what price can it be imported? Mr. Darwin informs us that at Arica, in Peru, the nitrate of soda is sold at the ship's side at 14*s.* the 100 lbs., or 15*s.* 6*d* a cwt.; and in this country it used to be sold at 18*s.* or 19*s.* though during the last year it has risen to 26*s.* and 28*s.* a cwt. We may suppose therefore, that 4*s.* or 5*s.* a cwt. would pay all expenses of freight, and leave a handsome profit to the importer. Now, Mr. Winterfeldt * states that the red and dark-gray varieties of the guano, those imported into this country, are worth 2*s.* 3*d.* a cwt. in Peru; in this country, therefore, from 7*s.* to 10*s.* a cwt. ought to be a remunerating price to the merchant, if Mr. Winterfeldt be correct.

It is true that an article is worth to the seller exactly what it will bring in the market, but it is of great importance, not only to the agriculture of the country, but to the speculators themselves, that the price of this commodity should be kept at a reasonable rate. Not only will many more be willing to try it on their farms, if the price be low, but the general demand for it will increase in proportion as the exact experimental farmer shall become satisfied that the use of it is attended with profit to himself.

Every man has a right to a fair return for his own labor, and to an adequate compensation for pecuniary risk; and those persons deserve especial compensation who have hazarded their money in importing a substance which, like guano, may minister to the most vital wants of the country; but those who, having themselves no pecuniary interest in practical farming, are yet desirous, as good citizens, to promote the growth of food as the foundation of national prosperity, may be excused in considering the chance of *great* profits to speculators, as subordinate to the general interests of the agriculture of the country.

III. Let us then advert to theory, and see the *highest* price which, according to its indications, the farmer ought to be called upon to pay for the guano.

We have seen that this substance is a mixture of various chemical compounds. It is a natural mixture; but an artificial mixture may be made which shall more or less completely imitate it. What would such a mixture cost at the present price of the several ingredients of which it consists? The phosphate of lime it contains exists abundantly in bones: the ammonia may be applied either in the form of sulphate of ammonia or of sal ammoniac, both of which are low in price: the common salt and sulphate of soda can be obtained at little cost; and the urea, being so small in quantity, may be either neglected altogether, or may be replaced by a little dried urine or night-soil (Poitevin's manure.) A mixture of this kind, equal in virtue to 4 cwt. of guano, would cost as follows:—

315 lbs. or 7 bushels of bone-dust, at 2*s.* 9*d.*	£0	19	3
100 lbs. of sulphate of ammonia, containing 34 lbs. of ammonia	0	15	0*
5 lbs. of pearl-ash	0	0	10
100 lbs. of common salt	0	2	0
10 lbs. of dry sulphate of soda	0	0	10
530 lbs., equal to 4 cwt. of guano.	£1	17	1½

To these it might be advisable to add 100 lbs. of chalk to aid in gradually converting the sulphate of ammonia into carbonate, in which state it may possibly be more immediately active upon the plant. This, however, is a matter for trial, as I am aware of very beneficial results having been obtained during the past season from the application of sal ammoniac in admixture with other substances, without the presence of chalk.

I consider the above mixture as likely not only to be equally efficient with 4 cwt. of guano, costing at present 5*l.*, but ultimately it may be more so; and this chiefly because in specifying the ingredients no account has been taken of the animal matter present in the bones, though the quantity of gelatine they contain is itself sufficient dur-

* "The red and dark-gray are worth 2*s.* 3*d.* a cwt. The white is sold in the port of Mollendo at 3*s.* 6*d.* a cwt.; and at times, as for instance during the war, it has brought as high a price as 12*s.*"—Winterfeldt.

* At the pleasure of the experimenter, a *portion* of the sulphate of ammonia may be replaced by nitrate of potash, in the proportion of about three of the nitrate to two of the sulphate.

ing its slow decay to yield about 30 lbs. of ammonia to the soil. I have not taken this into account, because the special and immediate action of guano seems to depend upon its containing, like farm-yard manure, ammonia ready formed, and thus prepared to act without delay on the plant to which it is applied. That growth which the ammonia of the sal ammoniac in our mixture is fitted to hasten and provoke, the ammonia which is afterwards slowly evolved from the decaying animal matter will carry forward and help on to maturity. The few pounds of potash in the mixture have been added, not because this substance is always present in the guano, but because it is known that nearly all plants require a certain small quantity of this alkali for the perfect developement of their several parts. Another advantage which will be possessed by the artificial mixture will be, that its constitution will be constant, and may always be calculated upon.

From these theoretical considerations, therefore, we should say that until its virtues are proved to be greater, beyond dispute, than those of the above or similar mixtures, the practical farmer ought not to purchase guano at a higher price than 20s. per cwt., a price which in the opinion of Mr. Pusey the farmer may probably afford to pay—which according to Mr. Winterfeldt would more than remunerate the importer—and below which, according to the chemist, an artificial guano of equal efficacy may be prepared in England, and *from the superabundant produce of our own manufactories.*

Of comparative experiments with guano and other manures.—But the absolute value of guano itself, as well as its relative value compared with other manures, can only be placed beyond dispute by actual and comparative trials of its efficacy in different soils and upon different crops. To be really useful and satisfactory these trials must be made according to some well-digested method, and the comparison must be made with known weights of other substances, the action and money value of which are known, and which from their constitution may be supposed to act on vegetation in a similar way. As I have elsewhere endeavored to draw the attention of practical men to the importance of well-devised and carefully executed experiments in practical agriculture*—not only to the general economy of the art of culture, but also to the establishment of a true theory of its various processes—I shall take the liberty of introducing a few suggestions in regard to the kind of experiments which appear to me most likely to yield results at once economically and theoretically useful.

Among those substances which owe one main part of their beneficial agency on vegetable life to the ammonia they contain or evolve, may be reckoned farm-yard manure, crushed bones, and rape-dust. As the nitrates also act upon plants in a way so far similar to ammonia as to yield nitrogen to them, the nitrates of potash and soda may be included in the list of substances with which it would be desirable to compare the action of the guano. The cost of all these substances is known,—they are all to a certain extent in general use,—and while comparative experiments accurately made by weight and measure would throw light on many obscure points in regard to the action of each of these manures,—the results obtained from every separate plot of ground would serve as so many points of comparison by means of which the absolute and relative value of the guano might be determined.

In the present state of our practical knowledge respecting this substance, it will be pronounced by every one to be desirable that its effect should be tried upon every kind of crop; but the propriety of this course is increased by our knowledge of its chemical constitution. It contains the greater part of the ingredients which are necessary to the growth of almost every variety of crop. It will doubtless prove as efficacious therefore to old pasture-land as to the rye-grass in Mr. Skirving's nursery, and to crops of corn as to Mr. Pusey's turnips; but experience alone can tell us to which it may be applied with profit to the farmer, and from what crops it will afford him the greatest return on a given soil.

I would propose therefore that it should be tried during an entire rotation to replace farm-yard manure and the other substances named, as well as against the mixture above described, which I shall distinguish by the name of *artificial guano.* The mode of making the experiments may be varied at the wish of the practical farmer, but they might be made in a way similar to that represented beneath, each square being a half or quarter acre or other accurately measured plot of land.

20 tons of Farm-yard Manure.	10 tons do. with 10 bushels of Bone-dust.	10 tons do. with 10 cwt. of Rape-dust.	
20 bushels of Bones with Ashes.	20 cwt. of Rape with Ashes.	10 cwt. of Rape with 3 cwt. of Guano.	
6 cwt. of Guano mixed with Chalk or Gypsum.	10 tons of Farm-yard Manure with 3 cwt. of Guano.	10 tons do. with 2 cwt. of Guano.	
6 cwt. of Artificial Guano.	10 tons of Farm-yard Manure with 3 cwt. of Artificial Guano.	10 tons do. with 2 cwt. of Artificial Guano.	

The practical farmer need not be deterred by the formidable array of experiments above suggested. He may try any two or three of them, and his results will be valuable in proportion to

* See a small tract published by Blackwood, under the title of "*Suggestions for experiments in practical agriculture.*"

the accuracy with which his land is measured and his manures and crops weighed. I have taken 20 tons of farm-yard manure as a standard, though in many highly farmed parts of the country no more than 15 tons are usually applied. Twenty bushels of bones are recommended by the Doncaster report, and I have lately found that in the Lothians 1 cwt. of rape-dust is considered to replace 1 ton of farm-yard manure. This proportion of course will vary with the quality of the latter manure; but, whatever quantity of this latter we take as the standard of comparison, it is easy to adjust the proportions of the other substances accordingly. I have not recommended any trial to be made with more than 6 cwt. of guano, because, where farm-yard manure is valued only at 6*s.* or 7*s.* per ton, 5 cwt. of the former would cost as much as 20 tons of the latter.

The above experiments are intended to be made with the green crop and continued during an entire rotation;* any pair of them, however, may be tried on single crops, whether of corn or of turnips and potatoes. In this way it ought also to be tried against nitrate of soda and against bones, upon seeds and upon old grass-lands. The modes in which such experiments may be made will readily suggest themselves to the intelligent farmer. *In all cases the results should be accurately recorded, and if possible published.*

I consider it of importance that an artificial mixture, similar to that above suggested, of which the composition is known, and which can anywhere and by any one easily be made, should be fairly tried against the guano;† because it does not appear, as some have been led to believe, that the supply of this substance on the coast of Peru is by any means inexhaustible.

According to Mr. Winterfeldt the supply of recent guano has diminished materially even in recent times; and in an extract from his letter already given he mentions one extensive deposite of the old guano in the island of Iquique, which was exhausted in 25 years by the local consumption only.

But the diminution is placed in a stronger light by Mariano de Rivero, in a paper published in the Spanish language, but from which an extract is given in Ferussac's Bulletin (sec. I., tom. xi., p. 84.) He says—

"The Spaniards permitted the wise ordinances of the Incas, which ensured the preservation of this valuable manure, to be entirely forgotten. The Peruvians are now aware of this great error, and see with anxiety the period approaching when the guano will no longer be obtained in sufficient quantity to meet the demands of the agriculture of the country. *The discovery of new deposites of the brown guano, which is of very ancient origin, is daily becoming more rare,* while the production of the recent white guano is rapidly diminishing, since, through the freedom of commerce, so many vessels have visited the coast and scared the birds which frequented them."*

If the above account is correct, it is the interest of Peru to prohibit the exportation of the guano; but the introduction of it into this country in the mean time will prove a great national service, if it shall teach us to imitate so valuable a natural production, and, by making available those articles of home manufacture which have hitherto been neglected by the agriculturist, to supply the lack of farm-yard manure, and thereby to raise a greater amount of food than we should otherwise be able to do. Thus at the same time will the chemical arts and the art of culture be bound together by still another tie, and the mutual dependence of all classes of the community, however apparently distinct their industrial occupations, be still more distinctly illustrated.

Durham, 20th October, 1841.

* By this I mean that the effect of these several manures applied *once for all* to the green crop at the commencement of the rotation, should be traced on each successive crop through the entire course of cropping.

† I have not suggested the comparative trial of such substances as those sold under the name of urate, animalized carbon, &c., because, though I have no doubt of their efficacy when prepared after a certain manner, yet the practical farmer has no guaranty that what he purchases this year shall prove equal in virtue to that which he applied to his land in a former season.

THE CULTURE OF SUGAR.

From the Philadelphia Public Ledger.

Until the production of sugar from the maple, and more recently from beets, the production of this *necessary* of human life was supposed to be confined to the tropics. But though maple sugar is the produce of temperate regions, its cultivation is necessarily too limited to supersede extensively the use of tropical or cane sugar, and this cultivation must decline with the settlement of the country. Most of the trees which afford sugar are found in the primitive forests; and as thirty years at least are required to produce a maple tree of sufficient size for sugar, the cultivation of sugar orchards by the present generation, for its own use, is impracticable, and we cannot expect that a people will labor for posterity, in a new country which demands all their labor for themselves in immediate returns. We may add that in our mode of clearing land of forests by *fire* as well as *steel*, the preservation of the spontaneous growth of maples is out of the question. Therefore we can only manufacture maple sugar in new settlements and by an expenditure of labor that might be more profitably employed. The whole quantity of sugar produced in the United States in 1840, was 155 millions of pounds. Of this quantity, Louisiana produced about 120 millions, Georgia about 330,000, and Florida about 275,000 pounds, the whole of which was doubtless cane sugar. This quantity, about 120½ millions, deducted from the whole quantity, leaves 34½ millions for maple and beet sugar. Of this quantity, New York produced 10 millions, Pennsylvania about 2¼ millions, Virginia about 1½ million, Kentucky about 1¼ million, Ohio about 6½ millions, Indiana about 3¾ millions, and Michigan about 1½ million; and of these 34½ millions, the whole was maple sugar, excepting, perhaps, a small quantity produced in Pennsylvania, in the vicinity of this city. The whole of this sugar was consumed at home; for notwithstanding all this production, 120 millions of

* See Poggendorf's Annalen, vol. xxi. p. 606.

pounds was imported for domestic consumption, the whole of which was cane sugar. Thus of 275 millions of pounds of sugar consumed in the United States, about 240 millions are cane sugar. These facts show that the quantity of maple sugar manufactured bears a small proportion to the whole consumption, and that this quantity must annually decline with the removal of the forests.

Of beet sugar, 150 millions of pounds are annually manufactured in Europe; but as cane sugar is cheaper, protecting duties are necessary for the cultivation of the former. But in the United States, the quantity of beet sugar produced is trifling and probably it will not become a substitute, extensively, for sugar cane. Nevertheless, our country does produce a species of sugar which might supersede entirely the consumption of cane sugar, foreign or domestic, and even become an article of exportation. *Indian corn* contains sugar in large quantities, and might be profitably cultivated for it in every part of the Union. According to Beaumé's *saccharometer*, or apparatus for ascertaining the quantity of saccharine matter in plants, the corn stalk reaches to 10 degrees of saccharine matter, which is three times greater than that of the beet, five times greater than that of the maple tree, and fully equal to the cane in the United States. Experiments prove that six quarts of the juice of corn stalks produce one quart of crystallized syrup, or sugar, which is a product of 16 per cent., while thirty-two quarts of maple sap will yield only one quart of syrup. And besides furnishing as great a proportion of saccharine matter as the cane, the corn stalk can be produced, for sugar, within 90 days, while the cane requires at least 18 months of careful and laborious cultivation to bring it to maturity.

To produce the greatest quantity of saccharine matter in corn stalks, the ear must be plucked so soon as it appears; and by this process, all the saccharine matter that would have been used in forming the ear, is retained in the stalk. One thousand pounds of sugar may easily be produced from an acre of corn. Those to whom this seems incredible, will remember that a bushel of ripe corn will weight about sixty pounds, and therefore that fifty bushels, an ordinary crop to the acre, will weight three thousand pounds. Then as nearly all the flour or meal of corn is convertible into starch, and as starch is convertible into more than its weight of sugar, one thousand pounds of sugar to three thousand pounds of corn is not an extravagant product. To this we may add that in some parts of the country, especially South Carolina, Georgia, Alabama, Mississippi, Louisiana and Florida, two crops yearly for sugar might easily be produced. By the removal of the ear so soon as it appears, this whole quantity of saccharine matter is retained in the stalk, in addition to the quantity which it contains when the corn is allowed to ripen.

By proper cultivation, we believe that fifteen hundred pounds of sugar might be produced from an acre, in a single crop, and not less than twenty-five hundred pounds in two crops. We must add that while the machinery for manufacturing cane sugar is cumbrous and expensive, that for corn sugar is light and cheap, the stalk requiring only one fifth of the pressure necessary for cane. Besides, cane being an exotic in the United States, only a small portion of it yields saccharine matter, while the whole of the corn stalk yields it, excepting the *spindle* or top. The stalks, after pressure, with the leaves, are worth enough, it is said, as food for cattle, to defray the expenses of cultivation.

Though no experiments have been made to test the value of corn stalks for sugar, when dried, we doubt not that they are as valuable for this purpose, as when green; for as nothing but the water evaporates in the process of drying, all the saccharine matter must remain; and by the process of straining, the stalk may afterwards be subjected to the press without any loss. This process of drying and subsequent straining is used in the cultivation of beets for sugar; and if it can be applied to corn stalks, as we believe, the cultivation of corn sugar will be greatly facilitated; for in that case, the manufacture can be postponed till the winter or end of the autumn, when most other agricultural labors are ended.

Corn being indigenous in all parts of the union, while the cane is an exotic, and confined to a small southern district, the cultivation of corn sugar may entirely supersede that of the latter. The average crop of sugar in Louisiana is 900 or 1000 pounds to the acre, about one third of the product in Cuba and other tropical regions. And besides, the capital necessary for cane sugar being great, it cannot be cultivated by landholders of moderate means; and of all modes of southern cultivation, cane sugar has been the least profitable. All parts of the United States are subject to frosts, and when they occur in Louisiana, where they are not uncommon, the sugar crop is destroyed or injured; and to escape them, the sugar planters are obliged, when the cane is ripe for cutting, to employ their laborers incessantly during day and night, in cutting and pressing. But on the sugar lands of the south, two crops of corn for sugar might be produced annually, before the appearance of frosts, both yielding 2500 or 3000 pounds of sugar. Hence, besides being a profitable crop in all other states, corn sugar would be a far more profitable crop than cane sugar in Louisiana. We commend this subject to the notice of sugar planters, and advise them to make an experiment in the cultivation of corn. Their preparations for the manufacture are already made in their machinery for cane sugar, and they would be merely required to raise the corn. In Louisiana, corn grows not less than twelve feet in height, and like all other plants produced in southern regions, must contain more saccharine matter than northern corn. Hence, if an acre of northern corn would yield, at the rate of fifty bushels of ripe corn to the acre, over one thousand pounds of sugar, an acre in Louisiana would yield fifteen hundred or two thousand pounds. Then if it be a profitable crop at the north, much more so will it be in Louisiana and other districts of the union where sugar cane is now cultivated.

According to Mr. Ellsworth's report, the quantity of corn produced in the union, in 1840, was 387 millions of bushels; and if the whole of this had been converted into sugar, at the rate of twenty pounds of sugar to the bushel of sixty pounds of corn, which is a very moderate esti-

mate, the product of sugar would have been 7740 millions of pounds. By twenty pounds of sugar to the bushel, we mean that the quantity of corn stalks that would have produced sixty pounds of ripe corn, will produce twenty pounds of sugar. Therefore, if only about a twenty-fourth part of this corn had been converted into sugar, the product would have equalled the whole quantity of sugar, foreign and domestic, consumed in the United States. This quantity, as we have already stated, is 270 millions of pounds; and at the rate of twenty pounds to the bushel, it would require 13½ millions of bushels. This being a small proportion to 387 millions of bushels, and at the rate of fifty bushels to the acre, and one crop annually, could be produced on only 275,000 acres of land. Then if 275,000 acres of land, cultivated for corn sugar will give a substitute for the whole quantity of sugar consumed in the United States, how boundless are their agricultural resources for sugar alone! With such a reserve, the south have no cause to tremble for the loss of their cotton crop for England, through the cultivation of cotton in India.

PROPER TREATMENT FOR CATTLE NEWLY BROUGHT TO THE SOUTH.

From the Ploughboy.

Mr. Editor—By giving publicity to the following letter you will confer a favor on those who feel an interest in improving their stock of cattle. It is superfluous to add that the great skill and acknowledged success of Col. Hampton, in rearing the finest stock in the state, entitle his opinions to be regarded as of the highest authority; and the liberality with which he has communicated the results of his experience entitles him to the thanks of this community. J. T.

Columbia, January 24, 1842.

My dear sir—Without detaining you with an apology, for so long a delay in answering your favor of the 31st ult., I proceed at once to the subject matter of your inquiries. All cattle imported from England, the north and the west, are very liable to be attacked by a fatal disease, which I take to be an inflammation of the brain.

Young cattle, from eight months to one year old, are less subject to it than those more advanced in life. If they survive the summer and autumn, I consider them safe, although great care should be taken of them the second season. They should be brought into the state as early in the fall as possible, kept in good growing condition through the winter, and in the spring be removed to a high healthy position, have easy access to pure water, and their pasture as much shaded as the nature of the ground will admit. In August and September they should be kept in a cool stable during the heat of the day, and at night also, the dew at that season being almost as injurious as the intense heat of the sun.

With these precautions, I think more than half would escape the disease, the first indication of which is usually a languid appearance of the animal, followed by the loss of appetite, short, quick breathing, with more or less fever, and not unfrequently accompanied by a cough.

I have hitherto considered this disease, when once established, incurable. I have recently learned, however, that by sawing off the horns, close to the head, nine out of ten would recover. In two cases only have I known the remedy to be tried, and in both the experiment was successful. I shall be highly gratified if any of these suggestions shall be useful to you or any of your friends; and wishing you entire success in your experiment, I am very respectfully and truly yours,

J. Terry, esq. W. Hampton.

FACTS IN HOG FEEDING.

From Colman's Fourth Report of the Agriculture of Massachusetts.

One of the farmers whom I visited had then in his sties three swine, whose average weight would equal four hundred pounds each. They were fed three times a day, with a mess of 12 quarts of meal to each per day, composed of the meal of oats and Indian corn, mixed in equal parts and stirred in cold water. The price of oats at that time was 42 cents per bushel,—of corn, 84 cents per bushel;—6 qts. of oatmeal would be cts. 8.4; 6 qts. of corn meal would be cts. 16.8, —total, 25 cents 2 mills each per day as the cost of keeping. The price of pork at that time was six to seven dollars per 100 lbs. A gain of two pounds a day, live weight, would much exceed the ordinary gain of a fattening hog, although, in a remarkable case, I have known the daily gain, for eighteen days in succession, to exceed three pounds. At two pounds a day, there must be a considerable loss in this feeding. The prices of grain, however, were above the usual prices; and the price of pork was depressed.

Another farmer, in fattening three swine, allowed them one peck of meal each per day. The mess was composed of Indian corn, buckwheat and oat meal, mixed in equal quantities. The price of corn was 84 cents; buckwheat, 56 cents; oats, 42 cents per bushel. One peck of this mixture cost fifteen cents.

One of the most exact and careful farmers in the county fattens his swine chiefly in the winter, so as to have them in the market in March, when pork generally bears a good price. He has close sties, which are kept with great neatness; his swine are fed with exactness and punctuality; and in severe weather, he endeavors, by closing the windows and doors, to keep up a moderate temperature in his sties by a fire in the furnace, where he cooks his food for his swine. Another farmer in Leverett, who makes excellent pork, prefers the winter fattening of swine, but is extremely careful that they shall not suffer from cold, his sties opening to the south, and being always abundantly littered. The farmer first alluded to has made trial of molasses for his swine, having purchased a condemned lot at a low price. He gave at the rate of half a pint per day to each hog, with great advantage as he supposed, though no accurate observation or test was made to determine the gain, and the proportion of that gain, if any, to be attributed to this article of food.

A farmer in Buckland considers ruta-baga, fed raw to swine, of equal value as raw potatoes. This judgment, he says, is the result of his own experience. A farmer in Hawley thinks swine

may be fatted to great advantage, when the price of pork is 10 cents in the market and corn is one dollar per bushel. This is rather a loose estimate, and I should not quote it, but for my great confidence in this farmer's long experience and careful judgment. An excellent farmer in Conway puts up his hogs to be fatted in August, and he greatly prefers pumpkins to potatoes. There is no doubt that the pumpkin is a very nutritious vegetable. A very large amount may be raised upon an acre. The difficulty lies in their preservation; but when they can be used to advantage early in the season, they are a very profitable crop.

A farmer in Charlemont says, that, after twelve years' experience, he deems apples, bushel for bushel or pound for pound, of equal value with potatoes for feeding swine. He prefers sweet apples, but is not confident that they have any advantage over sour apples.

The raising of pigs is spoken of by several farmers as an excellent business. This can seldom be done to advantage unless in connexion with a dairy. A farmer of Deerfield sold the pigs from two sows in one season for fifty-four dollars. Another in Gill sold the litters of two sows, in the spring, for fifty-nine dollars seventy-five cents. These results are, to a great extent, accidental; and depend on so many contingencies that no general rule can be drawn from them. A farmer in Northfield, on the 27th September, showed me three fine, thrifty swine, about one year old, nine tenths of whose feed, since the 13th May, had been obtained from one eighth of an acre of clover, cut and given to them in a green state.

SHEEP-KILLING DOGS.

From the Kentucky Farmer.

We noted, lately, that a petition had been laid before the House of Representatives, praying a tax on dogs, with the view of diminishing the destruction of sheep. The Commitee on Propositions and Grievances, to whom the petition was referred, have asked and obtained a discharge from the consideration of the subject; and as the petition was drawn by the Editor of this paper, leave has been obtained to withdraw it, for the purpose of printing it, as will be seen below. We drew up and offered the petition under a sense of duty; for our editorial position has furnished us facilities for learning that the farmers of the country suffer an enormous evil in the sheep-destroying propensities of dogs. We have received numerous letters and had countless verbal statements, from every quarter, of the loss annually sustained in this way; and we believed a due regard to an important interest of the state would have prompted the legislature to interpose some effectual remedy. The facts stated in the petition, we believe, are substantially true; the principles of the proposed law, in our judgment, are plainly defensible; and we deem the neglect of the legislature to protect the country from the evils incident to the enormous grievance complained of, a gross dereliction of duty. If a thousand tigers were transported from the jungles of Bengal and turned loose in the land to ravage and destroy the domestic animals, the propriety of making an organized effort, under legal sanction, for their destruction, could be defended by no arguments not applicable to that of destroying the superfluous roving dogs which swarm thoughout the land.

We are well aware that there is always attempted to be got up an odium against any one seriously moving a remedy against this evil; and we knew an instance of a most worthy man in a neighboring county, almost losing his election to the legislature for signing a petition on this very subject. Every species of opposition is offered to any movement of the sort. The good-natured crack jokes and provoke laughter and fun; the ill-natured swear most lugubriously; and there is another class, a sub-genus of political demagogues, who rave about "*rights*" and "*liberty*," but have no respect for the rights of others. But never a one condescends to favor with an argument against the justice, the policy, the expediency or necessity of an appropriate remedy for the intolerable evil.—*Ed. Ky. Far.*] * * * *

Petition of Tho. B. Stevenson, praying a tax on dogs.

The undersigned, holding a position which affords him many facilities for collecting information on the subject of this petition, is enabled to speak knowingly of an intolerable grievance suffered by a large number of the farmers of this Commonwealth and to which all are in danger of being subjected; and he conceives it his duty respectfully to present the subject to the General Assembly, praying such relief as it is in the power of legislation to grant.

The grievance complained of is the destruction of sheep by dogs. The undersigned has had much conversation with gentlemen from every quarter of the state, and he finds this grievance generally complained of. He believes that an annual loss of not less than one hundred thousand dollars is sustained by the country under this grievance. There is scarce a neighborhood in which farmers are not sufferers. Nor is the actual loss occasioned by the killing, wounding and scattering of flocks of sheep by dogs all that the country sustains in this matter. The business of wool-growing cannot be extended, without great if not entire risk, while the present evil remains. The undersigned perfectly well knows that, but for this oppressive grievance, flocks of sheep would be found grazing on the hill lands of the state, so well adapted for the raising of sheep, which are now lying idle and unproductive, because the owners fear to risk their flocks to the ravenous propensities of roving dogs. To say nothing of the intrinsic justice of removing this grievance, there is, in the present condition of our industrial interests, nothing more desirable and important than the extension of our means of production, and a change, to some extent, of our agricultural staples. These are few branches of industry of equal importance with the wool business; and its extension in Kentucky is demanded by every consideration of economy and regard for our domestic interests. And if we could extend our means of producing wool, the extension of our manufacturing interests would be as great as that of the agricultural. Our hill lands, now lying desolate and waste, can be made to sus-

tain flocks of sheep that would annually add untold thousands to our production; and their wilderness solitudes can become the abodes of a hardy, industrious and virtuous population. Yet the undersigned has known many sensible farmers, entertaining strong convictions of the practicability and productiveness of sheep-husbandry on our hill lands, utterly decline the business for no other reason than the fear of the destruction of their flocks by roving dogs. Scarce a day passes but we hear of their ravages. It is not a sufficient remedy that it is the common understanding that sheep-killing dogs may be killed wherever found. They are not always found; and if they were and all were destroyed, their destruction neither atones for the loss sustained, nor prevents other ill consequences. The evil that dogs do lives after them. A flock of sheep, once disturbed by night-prowling dogs, suffers probably greater loss than the death of a portion. The living are ever after more timid and fearful, and either run wild or grow diseased; so that, in either case, their value is seriously injured.

Every one of the least observation knows that there are at least four times as many dogs in the state as are necessary for any purpose of utility; and consequently at least three-fourths of them are not only actual consumers of food, depredators in a thousand ways, but a nuisance in all respects, to say nothing of their sheep-killing enormities. The undersigned does sincerely believe that it is the duty of the legislature to suppress these evils by severe taxation or otherwise; and any effective measure will be sanctioned alike by the wishes and interests of the people.

Not the least degree of hostility is felt by the undersigned towards dogs or their owners, when kept in proper numbers and duly trained for useful purposes. But it is utterly intolerable that the honest interests of productive industry are to be seriously injured by packs of supernumerary dogs. If severe taxation were adopted, the number of dogs would be reduced to that which would usefully serve the wants of the country; and they would then be trained for useful objects, kept at home and restrained from mischief; for it is seldom a dog attacks sheep on his owner's farm.

The danger from that horrible disease, hydrophobia, more terrible than death itself in its direst form, would be diminished by reducing the number of dogs. The life of one good citizen is worth infinitely more to the commonwealth than all the vagrant dogs that swarm in the land, making night hideous with their infernal howling, consuming the food of the land, committing innumerable depredations, and destroying flocks of innocent and useful sheep.

The undersigned prays the legislative interposition to remedy these evils in a manner at once effective and consistent with the rights and interests of all concerned. They who desire to keep dogs for purposes of utility, should be allowed to have them on the payment of a very moderate tax, such as a good citizen would cheerfully pay for a benefit secured and enjoyed under a law designed to remedy a great evil and protect the rights and interests of all. The undersigned is not entirely confident that the following scale of taxation would be precisely adequate to the desired object or strictly just to all interests; but he submits it as embodying the principles of a law which the wisdom of the General Assembly could render efficient and just.

The owner of one dog to be taxed one dollar; of two dogs, two dollars; of three dogs, four dollars; of four dogs, eight dollars: of five dogs, sixteen dollars: and so on. And all dogs unclaimed, or on which the tax is not paid, and others running at large, to be killed forthwith by any one. Respectfully submitted,

THO. B. STEVENSON.

BLACK THE WORST COLOR FOR PAINTING WOOD WORK IN THE OPEN AIR.

There is nothing that will prove this evil more than by observing the black streaks of a ship after being in a tropical climate for any length of time. It will be found that the wood round the fastenings is in a state of decay, while the white work is as sound as ever; the planks that are painted black will be found split in all directions, while the frequent necessity of caulking a ship in that situation likewise adds to the common destruction; and I am fully persuaded that a piece of wood painted white will be preserved from perishing as long again, if exposed to the weather, as a similar piece painted black, especially in a tropical climate. I have heard many men of considerable experience say, that black is good for nothing on wood, as it possesses no *body* to exclude the weather. This is indeed partly the case; but a far greater evil than this attends the use of black paint, which ought entirely to exclude its use on any work out of doors, viz. its property of absorbing heat. A black unpolished surface is the greatest absorber and radiator of heat known: while a white surface, on the other hand, is a bad absorber and radiator of the same; consequently, black paint is less preservative of wood than white. Wood having a black surface will imbibe considerably more heat in the same temperature of climate than if that surface were white; from which circumstance we may easily conclude that the pores of wood of any nature will have a tendency to expand and rend in all directions, when exposed under such circumstances; the water of course being admitted, causes a gradual and progressive decay, which must be imperceptibly increasing from every change of weather. The remedy to so great an evil is particularly simple, viz. by using white instead of black paint, which not only forms a better surface, but is a preventive to the action of heat, and is more impervious to the moisture. The saving of expense would also be immense; and I am convinced that men of practical experience will bear me out in my assertion. —*Trans. Society of Arts.*

EIGHTH AGRICULTURAL MEETING AT THE STATE HOUSE.

From the New England Farmer.

Subject—Manures.—Mr. Buckminster (Editor of Ploughman,) said he may be rather heterodox in some of his notions in regard to manures. But

he has spent much time *in the fields*, and would tell what he has found there. It is a common notion that there is nothing like *hog manure*; he does not believe it. Used once to think that horse manure was poor stuff—but if it be properly composted with litter and urine it will *last longer* than any other manure. We are deceived in regard to hog manure—it works *quick*—but does not last. One cow properly tended and littered will make twice as much manure as one hog. Neither will make much unless they are well fed.

Many old maxims are not sound, and such as are unsound should be discarded. Most people in letting farms, make it a rule that the *hay* shall not be sold. But he would let a tenant sell *half* the hay, if he would not raise grain. The grains are the great exhausters. You may make any farm manure itself, provided you sell half the hay, if you do not raise grain, and if you save all the liquid manure. Sheep manure he has always found to be light stuff—and where his sheep run upon the mowing lands in autumn, and feed close, he gets not more than half as much hay the next year as on other lands. Some say that a cow will eat as much as ten sheep: he would say she will eat but little more than five sheep.

Mr. Stanley, of Attleboro', said that people are often deceived in regard to their own practices. We put much more materials for manure into the hog pen than we put into the heap of cow manure. Did we mix as much muck, earth, &c. with the cow dung as we do with the hog dung, we should find that the barn manure would not last longer than that from the hog yard. If we put ten loads of materials into the yard for one hog, the manure will be weak; if we put but three or four, it will be good. It is best always to put in enough to absorb all the liquids. For each hog he would put in two or three loads as soon as the yard was cleaned out in the spring, and would add as much more at different times during the summer. If he wanted to put his hog manure on cold clay lands, he would put gravel into his hog yard.

Vegetable manures.—Many farmers miss it in not turning the sward often enough: much manure *grows* upon the land. But it will not grow upon the field for more than three or four years. This manure consists of the stubs, roots and leaves of the grass. There will be no more of it at the end of seven years, than at the end of four. Therefore if you do not plough up after mowing three or four years, you lose the opportunity of *making* in this way. The quantity of vegetable matter upon the acre is said to be about twelve tons.

A gentleman in his neighborhood, who is a good and successful farmer, puts half of his manure—the long manure—upon the sward, and turns it under. Manures also in the hill. Takes off the corn in autumn, harrows the ground, and puts in rye and hay seed. His crops of rye have been good, and his grass has done well.

Mr. Putnam (Editor) said the practice just described was such as he had followed for years. He turned down one half of his manure—the long manure—and let it remain there under sod for five or six years. The corn had done well—very well—and the grass (which he sowed among the corn in July,) had done well the first two years, and in the third and fourth held out better than it had ever done before on the same fields. This plan of turning half the manure under the sod, he liked on warm lands, but on cold ones he would keep it nearer the surface.

Mr. Buckminster would like to know what was the experience of farmers as to the comparative benefits of *spreading all* the manure for corn, and of putting a part in the hill. He used once to think that he could not bury his manure too deep, but he was mistaken. Has waited seven years to hear from some that he buried, but no accounts from it have yet been received. He thinks it better to form our manures into composts and keep it pretty near the surface.

Mr. Gardner, of Sekonk, said it is customary in his vicinity to spread part of the manure on the surface and plough it in—and to put part in the hill. The best farmers have been accustomed to do this, and by this process they obtain their best crops. The spreading of all the manure is now more common than formerly.

Mr. Putnam said he had made an experiment in 1839. Half the manure (4 cords per acre,) was turned under the sod. Then, on a part of the field, the remaining half of the manure was put in the hill; on another part the manure was spread on the surface of the furrows and harrowed in. The corn manured in the hill did best in June, was much the largest in the early part of July, but in October, the part where the manure was all spread gave 31 bushels, where that manured in the hill gave 30. Had he have judged by the eye, and with the impressions upon his mind made by the early part of the growth, he probably should have said that the part manured in the hill did best; but the half bushel told a different story.

Mr. Lathrop, of South Hadley, thinks the question, as to the proper *place* for the manure, turns upon the wetness or dryness of the soil. He would not manure in the hill on light lands, but he would on heavy. There can be no general rule.

He would advise every farmer to have his horse manure thrown into the hog yard; the hogs keep it from burning, and make it worth double what it would be if burned.

In his vicinity, much of the long manure is spread upon the mowing lands. These lands are also plastered, and then two good crops are taken from them each year. He alluded particularly to several lots of land which, thus treated, give four tons and more per acre, annually, for many successive years.

PARTICULAR RESULTS OF FARMING IN MASSACHUSETTS.

From Colman's Fourth Report of the Agriculture of Massachusetts.

Facts are in general so interesting and so important, that I am always desirous of recording them, leaving it to others to make such inferences from them as they may deem proper. My principal solicitude is, that they should be well attested, and of such a character as to suggest useful instruction to others. They are the only infallible teachers and their lessons cannot be controverted. It may be safely asserted that there is nothing which has been done which cannot be done again; and under the same circumstances and influences, the same results will follow. These

established truths render facts of so much importance, and make them the safest of all teachers.

Example 1.—Management of seven and a half acres of land in Northfield. The land is alluvial; of good quality; on the banks of the Connecticut.

In 1828, the land was leased; the proprietor to furnish fifty buck-loads of manure from his barn-yard; and to receive, as rent of the land, half of the whole product. He received half the top stalks, all the bottom stalks, and twenty-five bushels of corn per acre.

In 1829, the land was leased on the same terms, and he received as above the coarse fodder, and twenty-two and a half bushels of corn.

In 1830, the proprietor leased it for broom corn, and stipulated to deliver on the ground six loads of manure to the acre. The brush, prepared for market, one half the crop, which he received as rent, amounted to twenty-seven dollars per acre; price at which the brush sold in this case not ascertained.

In 1831, he leased it again for broom corn, delivering upon the land six loads of manure to the acre, at a cash rent of sixteen dollars per acre.

In 1832, without manure, he sowed it with oats, and obtained from thirty-three to thirty-five bushels to the acre, which he sold at forty-two cents per bushel.

In 1833, without manure, he obtained an average yield of twenty bushels of sound wheat to the acre, valued at one dollar fifty to one dollar seventy-five cents per bushel.

The land was valued at sixty dollars per acre; at which price, at that time, land of the same quality in the immediate vicinity was sold.

Summary per acre.

In 1828, 25 bushels of Indian corn, at 75 cts. per bushel,	$18 75
" 1829, 22½ do. do. do.	16 87½
" 1830, returns from broom corn sold,	27 00
" 1831, rent of land in cash,	16 00
" 1832, 24 bushels of oats, at 42 cents per bushel,	10 08
" 1833, 20 do. of wheat, at $1 50 cents,	30 00
	118 70½
Six years' interest upon 60 dollars, price per acre,	21 60
Net profit of six years upon each acre,	$97 10½

The manure was furnished on the farm, and the stalks and straw may be considered as a full equivalent for the manure, seed and thrashing.

2. Produce of three and a half acres of land in Deerfield street, in 1833.

Hay, 3½ tons, at 12 dollars per ton,	42 00
Winter wheat, 11 bushels, at $1 50 per bushel,	16 50
Stubble and clover, one ton, at 4 dollars per ton,	4 00
Corn fodder, three tons, valued at	10 00
Indian corn, one hundred and twenty bush. at 80 cts.	96 00
Potatoes, one hundred and seventeen bush. at 20 cts.	23 40
Apples, sixty bushels, at twelve and a half cents per bushel,	7 50
Pumpkins, one cart-load,	0 00
	$199 40

3. I give, in the subjoined case, the actual expenses of cultivating several lots of land on the same farm the same year, with the returns. The expenses include every thing until the delivery of crops in the barn, with the exception of thrashing the grain, and the interest upon the value of the land. I have myself affixed the value of the crops, as nearly as I could ascertain it at the prices then current in the county.

1. Four acres and 106 rods in Indian corn.

Whole expenses of cultivation,		$90 83
Returns—		
352 bush. of corn, at 75 cents,	264 00	
Corn fodder, ten tons, at $4	40 00	
		304 00

2. Three and a half acres in corn.

Whole expenses of cultivation,		109 75
Returns—		
Corn, 236½ bushels, at 75 cents per bushel,	177 37½	
Fodder, 9 tons, at 4 dollars,	36 00	
		213 37½

In the former case, gypsum and ashes only were used, charged at $5 50 cents; in the latter case, 35 loads of barn-manure were used, charged at one dollar per load.

3. Five acres in oats.

Expenses of cultivation and seed,		35 50
Returns—		
280 bushels oats, at 42 cents,	117 60	
Straw, say four tons, at $3	12 00	
		129 60

4. Five acres in rye.

Expenses and seed,		21 50
Returns—		
60 bushels, at one dollar per bushel,	60 00	
Straw, say four tons, at $3	12 00	
		72 00

5. Two and a half acres in winter wheat.

Expenses and seed,		13 75
Returns—		
20 bushels wheat, at $1 50,	30 00	
Straw, two tons, at 3 dollars,	6 00	
		36 00

6. Two and three-fourths acres in spring wheat.

Expenses of cultivation and seed,		15 58
Returns—		
38 bushels of wheat, at $1 50 cents per bushel,	57 00	
2 tons of straw, at 3 dollars,	6 00	
		63 00

7. Fourteen acres in grass, home lot.

Expenses of getting two crops, in both 45 tons,	65 00
Forty-five tons of hay, at 8 dollars per ton,	360 00

8. Seven and a half acres in grass, in meadow.

Expenses of getting the hay, 15 tons,	20 75
Value of the hay, 15 tons, at 8 dollars,	120 00

The foregoing may be considered as examples of extraordinary success. I give them as such. They are examples of extraordinary success and extraordinary skill and good management. The success is the result of the good management. The good management others can command; and consequently the same results are within their power. Men pretend that there is a great deal of "good luck" in these cases. There is very little of what may be termed good or bad luck in

this world's affairs, and these terms are mainly used to soothe a conscience troubled with a sense of its own recklessness, negligence or indolence.

INDIAN CORN FOR FODDER.

From the New Genesee Farmer.

The cultivation of Indian corn for fodder may be well recommended to the farmers, especially where pasturage is deficient, or in a season when the crop of hay is likely to be small. Among the farmers who supply the cities with milk, it is a favorite crop, and is given to their cows at night and morning to assist a short pasture. In such cases it is sowed at successive seasons, every week or fortnight, so that the crop may be coming on as needed. It is sometimes cut when it is knee-high, and then in general it will start a second time, so that another cutting may be obtained. This should not, however, be confidently relied upon. Where it is wanted for green feed, it is of course advisable not to cut it until the plant is in perfection; we do not mean until the seed is ripened, but until the leaves and stems are as abundant and large as they are likely to be; that is when the flower is protruded, and the ear formed, and yet no part of the plant has become too hard to be completely eaten up by the cattle. Every farmer, therefore, may make his calculation as to the time of planting. The earlier he plants, the sooner he will have the fodder and the more of it to give to his stock; and by planting at successive times according to his convenience, he may keep up a supply of succulent food to the very end of the season. None need be lost; and every leaf and stem of it should be saved, even after the frost has killed it.

We have seen the plant cultivated to great advantage for soiling cows; in many instances; in one where twenty cows were kept; in another where a hundred cows were soiled. In the latter case several acres were sown with corn for this purpose; and it was cut and brought into the barn as wanted. There was no feed of which the stock were more fond; none which produced more milk; and none obtained at a less expense. It was all cut short by a machine, and while gathered green every particle of it was consumed. When in the autumn it became dry it was steamed for the stock. Among the milk farmers, near the cities, its cultivation is constantly increasing.

We have known it likewise much used for store hogs. Where pasturage is deficient, or where they are kept in sties, no green food is more relished by them or more conducive to their thrift. In this case, however, it is of course given to them in a green and succulent state.

We have not known it cultivated extensively for winter fodder, but there is no reason why it should not be. In this case it would be desirable to sow it early, if we would have the largest crop, and let it come to what maturity it will. The value of well cured corn fodder for stock is settled. The cattle have determined the question long ago by the relish with which they eat it; and the good condition in which it keeps them. The amount of well dried corn fodder, including butts as well as tops, where the crop is fifty bushels, is generally estimated at two tons; this of the small yellow flint variety of corn; the southern gourd seed variety and the western corn produce a much larger amount. Farmers in general are disposed to estimate the fodder upon such an acre of corn, well saved, as equal, for any neat stock, to one ton of English hay. Some place it at one and a half ton; none lower than three fourths of a ton.

The only instance which has come within our knowledge, of ascertaining with any exactness the actual amount of fodder or stover upon an acre, was in Pennsylvania, where we infer the gourd seed variety was cultivated, and where the crop amounted to 66 bushels. In this case.

	Tons.	*cwt.*	*lbs.*
The blades, husks and tops, when cured, amounted to - -	1	6	13
Stalks and butts - - -	1	7	00
	2	13	13

How much could be obtained by sowing it exclusively for fodder, we have no means of determining with any accuracy.

Nor have we any certain prescription to give as to the amount of seed to be used for an acre; certainly not less than half a bushel, nor more than two bushels. Corn is a plant which, in rich soils, tillers abundantly or throws out many suckers, unless where it is very thickly sown, in which case it conforms to every other plant in its habits of growth, and runs up in a slender form like bushes in a thick swamp. Many persons advise to sow it broadcast, in which case it admits of no after cultivation; and the weeds, if the land is rich, will check its growth and fill the ground with their seeds. It is best to sow it in drills two feet apart, and quite thickly in the drills, scattering the seed over a space in the row, six inches or a foot in width. It may then be ploughed or passed through with a cultivator once at least; and in a measure kept clean from weeds. It is believed that as much fodder may in this way be obtained from an acre as if sown broadcast.

The land cannot be made too rich for it; and it need not be gathered until it is ripe. There may be a good many imperfect and some ripened ears among it; but the cattle will not like it the less on that account. The Irishman was asked how he kept his horse so sleek and fat; and "faith!" says honest Pat, "he has nothing but wheat straw, your honor, and that is not *half thrashed*." It is a prevalent opinion that the top stalks of Indian corn when cut in a succulent state, and cured quite green, are better than when left to ripen. It is believed that this is an error; as the experience of observing farmers, we think, will show that their cattle do better, prefer them, give more milk and show better thrift, when fed upon the butt stalks, that is the leaves and husks upon the butts after the corn has been gathered, than upon the top stalks gathered and cured in a green state, as above described. The fodder need not then be harvested until it is, as it is termed, nearly dead ripe. Corn fodder when cut green, especially late in the season, is cured with great difficulty; but if left to stand until it is either killed by the frost or reaches maturity, it is as easily saved as hay. In putting away corn fodder, we have found it advantageous to insert, occasionally, layers of wheat straw. The sweet flavor of the corn fodder is communicated in some measure to the straw; and the straw serves to keep the

corn fodder from being injured by heating. No fodder suffers more or sooner from wet or rain than corn fodder. Every possible pains should, therefore, be taken to avoid this; and it is a good way to hang as much of our corn fodder, as we have room for, on the beams and on poles extending over the barn floors, and in sheds where it will be out of the reach of the cattle.

As to the kind of corn to be sown, the southern gourd-seed or the western corn, will undoubtedly give the largest weight; but much of it will be in the butt, no part of which will the cattle eat. Our common northern small flint corn will yield a large amount to the acre, as it will bear thick sowing; and the main stalk is not so large but that a good deal of it will be eaten, especially if cut up.

HABITS OF THE CURCULIO, AND MEANS FOR ITS DESTRUCTION.

From the Magazine of Horticulture.

The *curculio* is one of the greatest enemies of the plum; indeed, in many sections of the country, the whole crop is frequently swept off by its attacks. When its habits are well known, however, a little care will enable us to rid our gardens of this insect, so destructive to stone fruit.

The curculio is a winged insect, which emerges from the ground about the time when the trees are in blossom, and punctures the fruit almost as soon as it is formed, depositing its eggs in the tender skin of the swollen germ. When the fruit has reached one third of its size, if we observe it closely, we shall discover the scar of this puncture made by the insect, in the shape of a semi-circle or small crescent, about a tenth of an inch in breadth. The egg has now taken the larva form, and the latter is working its way gradually to the stone or kernel of the fruit; as soon as it reaches this point, the fruit falls from the tree, and the worm now leaves it in a few days, and finds its way into the loose soil beneath the tree. Here it remains until the ensuing season, when it emerges in a winged form, and having deposited its eggs to provide for the perpetuity of its species, perishes.

As it is found that the curculio, though a winged insect, is not a very migratory one, the means taken to destroy it in one garden are not without efficacy, though the neighboring orchards may not receive the same care. As the fruit, when it falls from the tree, contains the larva, it is evident that if we destroy it before the insect has time to find its way into the soil, we shall destroy, with it, the curculio. In small gardens, it is sufficient to gather all the fallen fruit every morning, during the period of its fall from the tree, and throw it in the hog-pens, when the whole will be speedily consumed. In larger orchards, where it is practicable, the hogs may (the trees being protected) be turned in for the short time in the season while the fruit is dropping, and they will most effectually destroy the whole race of insects of the current season. Indeed, in large plum orchards, this practice is found a very effectual remedy for the attacks of the curculio.

In small gardens that have come under our notice, formerly much troubled with the attacks of this insect, where the practice of gathering the fruit and destroying it daily for a short period has been pursued, the insect has failed to make its appearance after a couple of years, and the trees have borne abundant crops of fine fruit. In addition to this, we would recommend the application of clay about the roots of plum trees, in very light sandy soil.

It is sometimes the case that the plum will be many years in coming into bearing, where the richness of the soil induces too great a luxuriance of growth. When this is the case, the ground should be partially removed from the roots, which should be pruned or reduced in number one fifth or one fourth, and the soil replaced. This should be done in the autumn, and will rarely fail in bringing about a profusion of blossom buds and a good crop of fruit. A. J. DOWNING.

Newburgh, N. Y., Feb. 1842.

ROTATION OF CROPS.

To the Editor of the Farmers' Register.

Shirley, March 8th, 1842.

The interesting and well-written communication on the "rotation of crops," under the signature of N., in the February number of the Farmers' Register for 1842, reminds me (as I see he quotes my five-field rotation) that I ought in candor to acknowledge the change I have made in it, and the reasons for it; and while I do so, I must pay the tribute so justly due to the author of "Rivanna," in the February number of the Farmers' Register, 1840, for his better judgment in recommending his five-shift rotation in preference to the one I at first adopted.

In 1840 I changed my four-field system to a five-field one, viz.: wheat, corn, wheat, clover, clover pastured off; but I found, the very first year, after grazing the second year's clover field heavily, to remedy insects, in consequence of the dry fall, it was almost impracticable to fallow it up for wheat. And as we generally have dry seasons at that time, it makes an insuperable objection to the system, for the labor of fallowing up a hard trampled field, in a dry season (the land breaking up in large clods, which clods have to be reduced by the rollers, harrows, hoes, &c.) is immense, on our stiff James river lands, and makes it insuperably objectionable. The crop of wheat succeeding, though, was very fine, the straw immense, and, where it did not lodge, very fine grain. I therefore last year changed the rotation to the one recommended so highly by Rivanna as the "beau ideal" of a system, viz.: corn, wheat, clover, wheat, clover, and have no doubt I shall find it a good one from the recommendation of such able authority. But I think if my lands had been as light and rolling as the author of N. describes his to be, I should have preferred the other five-field rotation, viz.: two years in clover before fallowing for wheat; as I consider it very important, from my late experience, that land should lie out longer in grass than one year. It is the great defect, I think, in our systems on James river, that the land does not lie out long enough in grass to resuscitate. With light land, such as N. describes his to be, the fallowing for wheat would never be very laborious; for light land never becomes very hard, however dry the season may be, and may be fallowed with ease, and I think with success, after two years in clover, the first,

allowed to fall and rot on the ground, as a manuring, and the second year pastured off, to leave a clean rich turf for wheat. The pasturing would certainly benefit light land very much, for trampling is very necessary to it to make wheat or clover. In fact white clover will not succeed on any land without trampling, and red clover is very much of the same nature, though not to the same degree. His land being rolling, would only have one hoe or washing crop in five years, and that would not wash it much when he leaves out a part through the winter for oats, provided he lays by his corn early, and lets it get grassy, to cover the land during winter, with the dry crop grass, and none the less corn would he make for it, as I believe there is more corn lost than made by late working.

I think there are some objections to Rivanna's system, as I propose to practise it. First, when you do not graze the clover at all, which is to be fallowed for wheat, as is my intention, and turn in all the clover, it is very difficult and tedious to plough, chokes the ploughs, and makes bad and slow work; and again, after a heavy crop of wheat on clover fallow, your clover is apt to fall from the wheat lodging, and killing the young clover, and then you have a bad pasture for the next year for your stock. The first objection Rivanna remedies by partial grazing; but that I do not wish to do, as I think it very important in the four or five-shift system either, to return all of the clover to the land in one of the years at least, and should prefer to encounter the trouble of turning in the clover to robbing the land of it; for however much the two systems have been lauded, I think there is very little doubt they are sufficiently exhausting on most of our Virginia lands to require all the clover once in the course of the rotation to resuscitate them; though with that, and the manure of the farm, I think good land will improve sufficiently fast for any reasonable man; and with the addition of marl, or lime, will improve very fast.

Another objection with me to Rivanna's partial grazing both clover fields, instead of rigidly grazing the pasture one only—it would defeat the chief object I had in view in changing my system from four to five fields, viz., remedying the insects in my land by grazing, in which I have great confidence.

Thus far I am very well pleased with Rivanna's rotation. Last year, (1841,) I had a very good clover pasture after the fallow wheat of the year before, and it stood the grazing admirably well, (having 80 head of cattle, 100 sheep, 100 hogs, including pigs, and occasionally 20 horses and mules, on 160 acres, very nearly two head to an acre,) and the grazing made this winter's ploughing for corn very good, as trampling makes winter ploughing easier, instead of rendering it more difficult, as it does summer fallowing for wheat. I have a very fine promise for pasture this coming summer, from last year's fallow wheat, and if I can only continue to have good pasture every year from the clover of the succeeding year after the fallow wheat, I shall be very well satisfied with the system.

I ought to mention that I only sow the cornfield wheat in clover, relying on the volunteer clover on the fallow wheat for the next year's pasture, which I suppose is the practice of Rivanna and all others who pursue his system, as there is generally plenty of volunteer clover on the fallow wheat, though I have always remarked that it was much less apt to turn out a good clover field than the corn-land wheat, sown in clover, owing to the lodging of the fallow more than the cornfield wheat, and also to the corn-land being much cleaner, as foul land is a great enemy to clover.

My system will vary somewhat from Rivanna's. Mine will be corn, wheat, clover, wheat, clover pasture heavily grazed, to go in corn again at the beginning of the next rotation. His is, corn, wheat, clover partially grazed, wheat, clover partially grazed, to go in corn again at the beginning of the next rotation. My object is, by heavily grazing to try to remedy the innumerable insects the clover has introduced in my land, such as clover worm, cut worm, wire worm, and all the variety of grubs we have in this country, which render it so difficult to pitch a crop of corn, and sometimes a crop of wheat too. For sometimes in the fall I have had my wheat very much injured by a little worm, resembling the wire worm, (which does so much injury to corn,) only a little shorter, which I called clover worm, from finding it in the clover fallow wheat, and not in the cornfield wheat at all.

HILL CARTER.

THE ADVANTAGES OF THE CLIMATE OF THE UNITED STATES OVER THAT OF ENGLAND.

From the New Genesee Farmer.

Your correspondent, W. Garbutt, of Wheatland, gives to the English farmer the advantage in length of season over the farmer of the United States, without even adverting to the very great advantage we have, in the superior stimulating power of our much warmer and more kindly season of vegetation. If by some change in the solar system, the power of terrestrial magnetism, or some involution in nature's course, the soil of England could be so far stimulated by the sun's rays as to produce Indian corn to perfection, should we any longer hear of her "starving population," reduced to live on the miserable bread made of damp mouldy grain? It is true that England has less severe cold weather and a shorter winter than we have; but look at the slow process of vegetation there as compared with that of the United States; her late harvest crowded into the short, cloudy, and even wet days of autumn, and it is not surprising that her corn is damp and mouldy. What would become of our ease-loving farmers if they had to encounter the cold, sour, wet climate, and slow vegetation of that country called merry, not sunny, England? Would they not be reduced from bacon and corn bread, to turnips and pea soup, from the delicious wheaten loaf and hot rolls, to oat cakes and potato broth?

Mr. Garbutt says that roots cannot be cultivated in this country to the same extent, *advantageously*, as in England. Very true, but then does not our Indian corn, that thrifty precocious king of edibles, (it being both food and fodder, oil and sugar,) render the like extensive cultivation of roots unnecessary? But we deny that roots may not be as easily cultivated in the United States as in England. If our more sunny champaign country is not as well suited to the turnip and potato, as cool and

misty England,—our early planted sugar beets never grew in greater perfection with us, than during the last summer, the hottest and driest season we have had in many years; and there is little doubt but that one acre of sugar beets is worth two acres of turnips.

We fully agree with Mr. Garbutt that it would be folly for our farmers to follow the rural economy of England in all its variety, but for very different reasons than a part of those set out in his otherwise interesting and well written article.

Waterloo, N. Y. S. W.

ADDRESS TO THE KANAWHA, MASON, AND CABELL AGRICULTURAL SOCIETY. GUYANDOTTE, Nov. 11, 1841.

By Gen. Peter H. Steenbergen, of Mason county.

Gentlemen of the Agricultural Society:—Another year has rolled on, and we are once more assembled under the rules of our organization. The spirit and feeling of its members present, together with the exhibitions on this occasion, will show whether it has been productive of all the advantages so earnestly desired by its formation.

Whatever of success and prosperity such institutions are calculated to insure will depend much upon the zeal, energy and indomitable perseverance of all who belong to the society. We should permit no trivial circumstance to delay us from promptly fulfilling the duties incident to our situation; suffer no rivalry for the prizes to estrange, or engender unpleasant feelings in their distribution. We should move on in peace and harmony, combined as brother farmers embarked in one common cause, and sailing under the flag of improvement.

It is difficult for me to determine what topic would be most acceptable to the majority of my friends present. This being the first meeting held in your county, and its good effects, if any, intended for your improvement, I have thought it best to take a review of some peculiarities existing in your soil, some causes operating to your benefit or injury, and thus correctness and truth will be equally applicable to all sections placed under similar circumstances. With your lands I am well acquainted. I will now notice the various shades and character of soil that your large county furnishes; and in doing so I beg of you to believe, that whatever remarks I may make are predicated upon a judgment matured and formed by a comparison of this section with that of others in our country.

Commencing then at this place, the town of Guyandotte, and descending the river, you are first struck with the infinite variety of soil your bottoms afford; first alluvial, then an elevated table of sandy land, and sunken ponds resting on a substratum of clay impervious to water. The uplands bordering on these are of excellent quality for grass or small grain. In what way can the owners of such various grades of soil best improve them? How should they be managed? How can their fertility be most readily increased?

I will notice them in the order named—Alluvial, first in character and value, resting on the river front and extending to the wet land or slash. This is the most easily reclaimed if exhausted by cultivation. Nothing more is required than deep ploughing and grass. Sow heavily with clover, graze lightly, and use the scythe to prevent weeds from maturing. Feed hay, cornstalks or straw on it, and you will soon recover all its lost fertility. Your wet land presents two varieties, the one an open prairie pond, originally covered with water, the other clothed with timber. I believe the art of man has never yet invented any means of rendering such lands available to useful purposes without first draining. Water impoverishes as rapidly as cultivation. In vain will you look for the healthy action of plants on land saturated with water, or reap the ameliorating influence of frosts in pulverizing your soil and adapting it to the growth of vegetables.

Such land in every instance should be well drained, by either open or secret ditches, using such as your resources will most readily command. If only thrown up in beds in the direction of the slope, and the centre furrows well cleared, the surface water will pass off, adding much to the value and production of the lands.

Your open prairie ponds are exceedingly rich, abounding in vegetable matter, and, when thoroughly drained and acted on by the sun and frost, will yield most abundantly. I am convinced that the surface of all wet lands, when reclaimed, sinks, and these ponds more than any other, occasioned by a greater decomposition on their exposure to the atmosphere. Hence open ditches, that when first cut answered the purpose, will have repeatedly to be deepened as your land settles; for you need expect no permanent improvement until you have thoroughly commanded the water.

On the subject of wet land, and the great importance of thorough draining, I have never seen a better illustration of its happy effects, than an anecdote given by the late Judge Buel. "An acquaintance called upon a Scotch farmer, whose farm had been under-drained, and being informed that the improvement cost sixteen dollars an acre, till having been used, remarked that it was a costly improvement. 'Yes,' was the farmer's reply, 'but it cost a deal mair *not to do it!*' which he illustrated by pointing to an adjoining farm, like situated, which had not been drained, and was overgrown with rushes and sedgegrass, and then to his own fields teeming with luxuriance and rich in the indications of an abundant harvest."

Those elevated tables of sandy land, so common to the Ohio, many of which now look like the sterile and worn out fields of the lower part of the state, have once, as I have often been informed by the first settlers, been the most beautiful part of all our bottoms. Before the hand of man had thrown them open to the sun, they were carpeted with wild grass and pea vines, looking like some splendid park, with all its undergrowth removed, well stocked with deer. Settlements commenced, those lands were soon cleared; but the constant and immense demands for grain to supply the Kentucky drovers, impelled their owners to the ruinous practice of repeated and continued corn raising, until they have nearly exhausted the whole life blood from them, and will now require that mode of treatment which modern

science in improvement has taught will successfully reclaim their fertility.

I labored under a strange delusion when I first settled in this country. We have lands on our farm exactly similar to those I am now describing, and we then believed them almost useless, that in consequence of their open sandy character nothing could be done to restore them, where once exhausted, or even to make tolerable crops, when first cleared and brought into active use.

The best plan that I can devise for the benefit of the owners of such property, is to give our own experience, when placed exactly under similar circumstances.

I vouch for the accuracy of every statement here made, and would thank gentlemen to call on us and have an ocular demonstration of its correctness. When my connexion, Mr. Beale, first got possession of his farm, a tenant had previously cleared about thirty acres of his sandy land, and had then absolutely worn it out, the last crop of rye he sowed producing less than five bushels to the acre. The whole of this field was covered with running, and the fence corners filled with standing, briers; not one single spear of grass sprung up or made its appearance on any part of the improvements. He then possessed no other cleared land, all the balance of his estate being an entire forest. On this spot he placed his dwelling. And then the question arose with him, what was the first move to restore the fertility of this land? How shall I accomplish it? Where are my resources of manure to come from? The balance of my land is in woods, and I must make this land, by its own recuperative energy, spring into life and usefulness again.

He commenced operations by applying his strong horses to a good plough obtained from Pittsburgh, and breaking the soil deeper than ever his tenant had previously ploughed, sowed small grain in September with clover and timothy. Yes, timothy on that poor sand bank! Most of the seed grew. A sorry crop of grain followed of course, but his grass seed had fortunately taken well, and in that he saw the germ of future fertility. It was lightly grazed the first year; the scythe applied to the briers in August. His stock added by their droppings a powerful auxiliary well prepared.

That grass remained three years, subject to the same treatment, and was then turned under. A wheat crop followed, that, I well recollect, was abundant. Clover and timothy were again sown, with some green-sward that he obtained from Kentucky. By this time he had cleared some of his front bottoms, and commenced feeding his fodder from them on those exhausted fields, now well set in sod. This process of feeding in the winter, and mowing any briers or weeds that spring up in the summer, was continued until he left our country and passed his estate to his son. At that time those exhausted sandy fields were brought to such a state of fertility, that the green-sward had taken entire possession of all the clover and timothy, and was seen lodging in all directions over the field, having eradicated entirely the briers, leaving not one stalk as a memorial of its former desolation.

Now for the benefits and subsequent profits that his son has been enabled to enjoy, from the admirable course of treatment formerly given to this land. He ploughed all up, and took two successive crops of corn, each averaging at least fifty bushels to the acre. It was then sown in wheat, clover and timothy, giving a good yield of wheat, and taking well in grass, remaining but one year in sod, his fat cattle being fed on it in the winter. It was again turned over, and two more successive crops of corn, equally good, followed by wheat and grass. Continuing two years and fed on in the winter as usual, he last spring ploughed again for corn, and has at this time a crop almost sufficient to take the premium to be awarded on this occasion, at a minimum of one hundred bushels to the acre.

I must explain, that although the measurement has been made in the field of this sandy land, yet the spot measured for the premium was naturally richer ground than the general average of the remaining portion: but I have no hesitation in asserting, that at this moment, on an average square acre of land in the lot so previously exhausted, there is standing at least sixty bushels of corn to the acre.

You will observe by this statement, that after the renovation of the sand, six crops, of grain, (four of corn and two of wheat,) have been taken in seven successive years. Then follows three years in grass, and thus it is now again in corn, clothed with the best crop it has ever produced.

What think you now of worn out sandy lands? Do you believe you possess any more completely prostrated than that I have accurately described above? Are you willing to enter upon the career of improvement? If you are, here then is an example worthy your imitation, fear not the result. You have seen what judgment and preseverance has accomplished.

While on this subject, I will state another experiment now in operation on exactly a similar character of land. The growth was all black oak and hickory, the ground so porous and sandy, that in early times I have frequently taken my ramrod from my rifle and without difficulty thrust the whole in the earth. How would you undertake to make such soil yield its hundreds? Now for the process. The timber was all killed, the undergrowth taken out, sowed in grass seed and ripe hay fed over the whole, to form a good sod immediately. The land was then grazed with cattle, and fed over occasionally during the winters. In six years succeeding the girdling, when after the bark and brush had been principally torn off by the storms and trod in pieces under the feet of the cattle, all the standing timber was cut down and burned, and the whole mass of vegetable matter thus collected and now nearly decomposed, turned in with the sod last year.

What think you was the average yield of the first crop? I am sure at least sixty bushels to the acre. Hogs were then turned in, and consumed the standing corn on the field. The balance of the winter and part of the spring fattening cattle were fed on the same lot with cut up corn and fodder until the earth was nearly covered over with litter. All was again this season turned under, and at this moment there stands upon it a crop of corn, some shocks of which have been husked, showing a yield of upwards of seventy bushels to the acre. The same process is again

to be applied the ensuing winter, with this difference, that in the present year, the corn has been cut up and will now have to be removed and consumed on grass land adjoining, the cattle will then be put on, and other corn and fodder brought and fed in the same place. There are two lots of ten acres each of that character of land, kept as winter and spring feeding lots. It is intended to try fairly the experiment, whether they will not produce corn every year in succession, and continue to increase in fertility while under that course of management. Sandy land is well known to improve under the operation of treading, it compacts the soil, rendered more tenacious: and what would succeed with it, is death to clay, making it utterly useless until pulverized by frost.

I have made this statement for the sole purpose of bringing into public view, the true value of that character of land when judiciously managed.

I am not the operator; it has passed under my own eyes, and I only claim to have aided by frequent consultation in the first successful experiment, that once accomplished gave the key to the subsequent course now in progress of execution, the result of which you will learn at some future time.

There is below here, as well as in our own county, a large body of similar land, and wherever there is a connexion with some rich alluvial front bottom, you have the means at command to restore its original fertility. Our best lands, as before remarked, possess within themselves the germ of their own restoration; you gain it by deep ploughing, followed by grass. All their production should be removed and consumed on your secondary soil. You will then observe with pleasure the great advantage a small covering in winter will produce in succeeding crops, and the efficient aid it furnishes to enable grass to take root. Once obtain this powerful auxiliary in restoring exhausted, or retaining the virtue of rich soil, and time and judgment will accomplish all your require.

There is on every farm some peculiarity of soil and position, an endless change and variety of circumstances, daily requiring the use of skill and experience to convert them to practical benefit. I would therefore recommend, that the farming publications should be taken by every man who expects to make his living or his fortune by the cultivation of the earth, for through them he will gain the first requisite of his profession, food for reflection, deep reflection, seeking cause from effects.

My intercourse heretofore, with other parts of your county, enables me to sketch some of the prominent features of its soil and character. Pursuing our way to the south part, I find the lands on the various forks of the Twelve Pole, and particularly that portion about the divide of the sandy waters, well adapted to farming purposes. It may rank high as a grazing country, whenever the present occupants shall cease their scourging operations of raising corn on hill sides, and convert them into blooming luxuriant pastures.

There is no better index to the farming pursuits of a country, than is evidenced by the character of their stock thrown into market. In early times, the mountain range was the beneficent resort of all, and is now nearly exhausted, still no preparations have been made for pastures to take its place. Hence, every succeeding year the stock decreases in size, and will continue to depreciate until a new era shall cover every hill and every hollow with teeming grass for their support. Your soil and advantages will justify these remarks, and for the evidence of its practicability and success I may refer you to your neighbors in Kentucky.

In examining the Guyandotte and some of its tributaries, I find that its bottoms have been exceedingly rich and productive, but that the same temptation to over cropping in corn, occasioned by the high prices obtained on the road, could not be resisted, and they have continued the suicidal policy of corn after corn in rapid succession, until they are now left with a diminished return of scarce half its original production.

Can it be good policy in any farmer thus to persist in an operation, that yearly lessens the remuneration of labor? I should think not. How will you remedy the evil? What course of husbandry should be adopted?

Some will contend that it is necessary to keep all their good land in corn, and that, even, if only one third should be laid down in grass for improvement, the balance will not yield sufficient for their consumption. Can you think of no plan to save this depreciation for a year or more; or to stimulate the two thirds in cultivation to produce what you now gather from the whole?

Reflect, have you no manure at command? Is there none to be obtained in this village? Can you not quantity the amount in your barn yard, sufficient to cover over one half of your corn land? And if thus enriched and well cultivated, may you not reasonably expect a return adequate to your demands, while your grass is restoring the balance.

A Pennsylvania German, or perhaps an eastern farmer, would find a resource in the alluvial deposite on your banks, which when applied to his corn land would keep up its fertility, until time was gained on the other for its restoration by grass. The tributary Mud river has suffered much from the same course of management, and its fertility materially affected from similiar causes. I saw there, in several places immense amounts of rich alluvial deposite, which if properly applied would be held in high estimation.

Pursuing the road through Teay's Valley, it presents some singular geological features, and were I now in search of hypothesis and proof to sustain the igneous action of the Huttonian theory, from the energy of internal fire and upheavings of the crust of the earth, I know no place near us that affords a finer field for the display of the imagination, or that presents stronger evidences of some great and wonderful alteration from its original position. How shall we account for the river rocks, rounded by attrition, imbedded in sand and pebbles, placed on an elevation two hundred feet above the level of the Ohio? How for the stratified rocks changing their angle of inclination? The inference is irresistible, that it has at some period been the bed of a lake or river, and that some convulsion has raised the earth and compelled the water to seek its course to the ocean through other channels. But enough of this; my business is with the surface as now existing, and

the use to which its occupants are converting it.

This valley on its first settlement must have presented a beautiful and attractive appearance. It abounds in springs, is gently undulating, only swelling in vales sufficient to carry off its redundant waters. Here too are seen the evil effects of severe cropping, reducing parts to an almost hopeless waste; but the hand of desolation will be arrested, for the march of improvement is onward and progressing. The attention of the traveller in passing is arrested by the evidence of what zeal and energy can accomplish. A worthy and enterprising member of our society, recoiling from the desolating course of his predecessors, and bursting through the shackles of an exploded system, has set an example of improvement that well entitles him to be hailed as a friend to the best interests of his country. I hope no apology is needed for this public expression of my approbation where I think it so justly deserved. There has been another example of successful improvement in the upper part of the valley, on a different character of soil, that was much admired for a period, until finally blighted and extinguished.

A gentleman, now a resident of Mason and then the owner of that estate, who was remarkable for his energy and industry, was the first to clothe a naked soil in all the blushing glory of rank and luxuriant clover.

He sold the property, and since then other councils and other plans have been pursued. I lately passed by that estate, and really it seemed to me, that some southern sirocco had swept over it, its devastating influence, withering and parching out every vestige of that beauty, which was the delight and admiration of all who saw it. I have now taken a cursory view of parts of your county, pointed out some facilities at your command for its improvement, and would finally say to those who are reviving their exhausted lands by grass—go on, increase the quantity sown until you cover all not required for the plough. Your example will eventually be followed by those who are desirous to share with you the rich reward you will certainly reap. Continue to inclose your wood land—cut out the under brush, sow it thick with seed. A good example is furnished you, by a countyman, a spirited member of our society, who has now thousands under fence, and every revolving year is adding to his almost unlimited means for extension.

A LIST OF PREMIUMS

Awarded at the annual meeting of the Mason, Cabell and Kanawha Agricultural Society, held in the town of Guyandotte, on Thursday, the 11th November, 1841.

To Gen. P. H. Steenbergen, bull *Rockingham*, Durham,	$20 00
James Shelton, 1 year old bull	8 00
Dr. Benjamin Brown, bull calf	5 00
George Moore, cow	10 00
Sampson Landers, 2 year old heifer	5 00
Washington Shelton, 1 year old heifer	5 00
John Morriss, stallion [by Greybeard]	10 00
James Y. Quarrier, 2 year old colt Prince Albert	7 50
Dr. Benjamin Brown, 1 year old colt by Sir William	5 00
J. Y. Quarrier, brood mare, dam of P. Albert	7 50
John Morriss, sucking colt by Young Grayb'd	5 00
Roman Manager, Berkshire boar	5 00
A. L. Doolittle do sow	5 00
Joseph Nagle, ram, Bridgewater	5 00
do ewe do	5 00
John Capehart, acre of corn, 114 bushels 7 qts*	25 00
John Morriss, acre of meadow, 6482 lbs. timothy,	10 00
John Capehart, best sample tobacco, (very good)	10 00
Mrs. Frances Moore, of Mason, domestic carpet	10 00
Mrs. Lucy Matthews, of Kan'a, rag carpet	5 00
Mrs. Sarah Doolittle, of Cabell, pair blankets	5 00
Mrs. Frances Moore, of Mason, piece of flannel	5 00
do do piece of jeanes	5 00
do do fancy bedquilt	5 00
Miss Olivia Holdridge, of Cabell, silk stockings	2 50

Articles for which premiums were not previously awarded, but pronounced by the judges highly deserving attention:

Mrs. Lucy Matthews, a very fine silk shawl, grown, spun, and manufactured by herself.

Miss Abigail S. Adam, of Cabell, a rich hearth rug and 2d best quilt.

Miss Sarah Poor, of Cabell, a fine woollen shawl, 5.4 square.

Mrs. Sarah Couch, of Mason, a rich toilet cover.

Miss Johanette Magnes, of Cabell, four infant net caps, very rich; and best piece of cotton hose.

Miss Leonora Chapman, of Cabell, the best specimen of sowing silk.

Mrs. Mary A. Nixon, of Cabell, a very fine palm leaf hat.

Ambrose L. Doolittle, three barrels cocoons.

Miss Julia A. Wright, of Cabell, presented a very fine speciman of race ginger cultivated by herself.

SILK CULTURE IN EAST TENNESSEE.

From the Tennessee Agriculturist.

The following extract handed us by a friend, from the most experienced silk culturist in Tennessee, we hope will be interesting to many of our readers:

Rotherwood, January 4th, 1842.

Dear sir:—In reply to your questions on the progress of the silk culture, &c., I remark, that notwithstanding the gloomy aspect of moneyed matters for some time past has deterred from all adventure, the silk business is now in a fairer

* There were three other competitors for this premium: Samuel L. Alexander produced evidence of having raised 112 bushels to the acre; Charles Beale 101½, and Morgan Moore 100.

way of success than at any former period. I have bought between $1500 and $2000 worth of cocoons the last year, and have reeled between 300 and 400 pounds of silk, which I have sent to Philadelphia, and am now waiting the result of sales of a large part recently sent. The feeding of worms the last season in East Tennessee was highly encouraging, although there were some failures. I have now no doubt of its being a branch of agriculture with us of no small ultimate importance. I was not so successful in feeding as some of my neighbors, owing I think principally to the dampness of the dirt floor to my shed. I have tried Mr. Morris' plan. There is nothing essentially new in it, and I do not like it. I have no idea of its general adoption. I have tried many ways of feeding and am not yet decided which is the best of several. I am rather in favor of the Turkish mode, viz: to feed with the branches piled on, the higher the better, never clean at all, and permit the worms to spin in the branches. This I believe the cheapest way. The cocoons are equally good and the fixtures of trifling cost. Indeed the floor may do for the first shelf. I ought to say, however, that the most successful feeding last season was on solid shelves and with the plucked leaf. I do not deem the question settled between these modes; because the Turkish plan has not been as fairly tested as the other. You can obtain peanut eggs of the best variety next spring by writing to me. Price I suppose about $5. Yours, respectfully,

FREDERICK A. ROSS.

AN ESSAY ON GRASS CULTURE.

For the Farmers' Register.

The cultivation of the grasses has but recently received much attention, in what is usually called eastern or lower Virginia. In this section of country, almost the sole dependence for provender has been on the offal of corn. Indeed the general opinion, until within a few years past, has been, that the grasses would not succeed well among us. How this opinion became so general, and why it was so long continued, I am at a loss to conjecture; for it is a fact, that in this portion of country there are vast quantities of land admirably adapted to this crop, whilst at the same time they will produce no other. Such lands have therefore hitherto been useless and worse than useless; for instead of adding to the value of our farms, they have only marred their beauty, and furnished so many eye-sores on the same. Of this kind were all the spring branches, and other streams, and marshes and low sunken places, which were permitted to remain in a state of nature, and to luxuriate in all the varieties of their own spontaneous productions. It seems never to have occurred to our worthy ancestors that, simply by ditching these places, the superfluous waters might be drawn off and in this manner rendered the most beautiful and valuable portions of their farms: but the son received the estate, just as it was transmitted to him by his father, and he in his turn, left it to his son in all its natural deformity.

But I am happy to say, that a spirit of improvement begins now to manifest itself among us. Whether it is that the high lands are so exhausted, that they will no longer furnish a support, or that an unwonted impulse has been given to this matter by means of agricultural societies and agricultural publications, the fact is that a great change has taken place for the better. People now begin to feel and to appreciate the value of grass crops; and they will admit that they never knew what it was to live in plenty and comfort, till they had an abundance of hay for their stock. Instead therefore of long lines of unreclaimed land on both sides of streams, instead of large bodies of sunken land covered with stagnant waters, sending forth pestilence and death every fall, these unsightly places are reduced to beauty and order. The water which was formerly permitted to spread abroad, the habitation of filth and disease, is now restrained in narrow ditches; and the lands which once produced nothing but bulrushes and other pests are now covered with rich crops of nutritious grasses. This beautiful state of things, I am sorry to say, is as yet just in its embryo among us. Much, very much, remains yet to be done. A few enterprising individuals, scattered here and there, in our widely extended waste, have showed this noble example. A mere *beginning* however has as yet been effected, whilst thousands and tens of thousands of acres are still in all their natural deformity. It is with the view of correcting this great and sore evil, that I write this essay; and if by means of it one single ditch is dug, or a single acre is reclaimed and brought into successful cultivation, I shall feel myself amply compensated for my trouble.

With these introductory remarks, I proceed to consider,

1st. Which of the various grasses it is most expedient to cultivate; and,

2d. The peculiar cultivation which experience shows is best adapted to success in this crop.

Of grasses there are a great many varieties, amounting to some hundreds and perhaps thousands. It is not my object to ascertain their precise number; nor is it my intention to present the few that I shall notice under their various botanic names. In fact, I intend this as a simple plain treatise, which, by the use of common names and the most common language, will be perfectly intelligible to every one.

It will be conceded on all hands, that of the very great variety of grasses, comparatively very few are of any special value. The great majority of them, however important to cover the land, and to furnish food in their tender state, are of no value whatever as a crop. Indeed most of them can be regarded in no other light than as mere pests, and therefore are to be ranked among thorns, briers and thistles, with which the earth was cursed, in punishment for the sins of mankind. These are so well known, that I consider it wholly unnecessary to point them out. But among the numerous family of grasses there are a few which, upon trial, are found to be of very great value. Of these, the common red clover deservedly claims the first rank. This grass is especially valuable on several accounts. When properly managed (of which more hereafter) it certainly makes a most nutritious hay, of which stock of every kind are very fond, and on which they thrive remarkably well. In addi-

tion to this, it is found to be the very best enricher of land when turned in, in a green state. All crops thrive well on a clover lay. The best crops of wheat and corn are uniformly taken from the clover fields. Indeed, the farmer considers his work as pretty well done when he can get his land in a state to produce clover freely. It not only throws forth large quantities of nutritious stems and leaves, but each plant has a long tap root, which penetrates to a great depth; so that the whole land, both above and below the surface, is completely occupied with it, and many are of the opinion, that the root contributes as much nutriment to the land as the top. This grass is rendered, in many situations, especially above tide-water, vastly more luxuriant by applications of small quantities of gypsum. Two or three bushels to the acre, applied in early spring, are often found greatly to increase the crop. In eastern Virginia, however, lime or marl, or ashes, is a much safer reliance. If alkalies be present in sufficient quantities, it will succeed well in almost any soil, except it be too wet, and when it has taken a firm hold, it is almost impossible to eradicate it. I have known seeds to vegetate after they have lain dormant at least ten years in the land. One sowing on good land, kept in a state of constant fertility, is ordinarily sufficient for all time.

The next grass which I propose to consider is what is commonly called the Kentucky blue grass. No doubt seems now to exist, that this grass is identically the same with that which abounds so much in all rich soils, throughout our whole state, and is known among us by the common name of green-sward or blue grass. There is however a difference, between these two grasses; but it requires a botanist to point it out. In a practical treatise of this kind, this difference is of very little consequence.

This grass, to the western farmer, is of immense importance, not on account of the crops of hay which it yields, but the rich pasturage which it furnishes. It is indeed one chief source of the western man's wealth. The time has been when New England was considered the best grazing country in America. The best cattle were found there, and large numbers of mules were exported to the West Indies. But since the introduction of this grass into the west, Kentucky and Ohio have evidently taken the lead. There is no doubt that these two states now furnish a larger number of fine animals than any other section of our country. Large numbers of horses and mules, great droves of cattle, and still greater droves of hogs, are driven every year from those states to find a market in the east. And all these animals depend, in a great measure, upon this rich nutritious grass.

And here it is a subject of interesting inquiry, may not this rich grass be turned to a profitable account among us also? It has already been remarked, that it grows every where in our state. I have seen it on the mountain top, and in the valley below. It succeeds well in all rich soils, both above and below tide-water. A fertile soil then is the only thing that is wanting to ensure success. Now it has occurred to me, that those farmers who have more land than they can cultivate (and great multitudes are in this situation) might turn their superfluous lands to great profit, by getting them well set in this grass. If the means exist, the process is a very simple one; and if the means do not exist, no farmer ought to rest satisfied till he has them. But it is not my intention to enter on that broad and extensive subject involved in the improvement of land. I would simply observe, that where marl exists, (and it abounds almost every where in lower Virginia,) stop up the gullies, if there are any, grub up the young pines and other rubbish that has taken possession of the worn out old fields; plough *deeply*, then cast on the marl; sow clover seed and harrow them in, and a foundation is at once laid for improvement. In two years, the clover will in a great measure disappear, and the green-sward will begin to take its place. The probability is that in many parts of the field there will be neither clover nor green-sward. Such places require further aid. But by persevering in this course, the whole field may ultimately be reduced to fertility and beauty, and in time the whole farm may be greatly improved.

But what is to be done when marl cannot be procured, and where the crops require all the manure that can be commanded? The only remedy in this case is *to make more manure*. Nor let any one say that this is impracticable. I venture to affirm, that not one in fifty among us makes *half* as much manure as he might and ought to make. The plan is simply this: increase your crops; this will enable you to increase your stock, and then a foundation is laid for increased manures.

It will be perceived that the above remarks apply only to those who have superfluous lands. It is obvious that all such lands are vastly more valuable in pasture, than to remain as exhausted old fields.

But in this section of country, and especially in the neighborhood of our towns and cities, there are also many small farms. Here it would be very bad policy to devote much if any of our lands to mere grazing; and here the green-sward, instead of being a blessing, is a mere pest. In all *tillage* lands, as a general rule, it is an unwelcome visitant. This is particularly the case in all the meadows in which we wish to cultivate the artificial grasses. There it is one of our greatest plagues, for such is the tenacity of its hold, and such is the rapidity with which it spreads, that it speedily displaces every thing before it. But as a mere pasture grass, I believe that its equal, both in firmness of sod, and richness of nutriment, is not to be found in the whole catalogue of grasses.

Some time ago I was much amused, and I hope profited, in looking over an analysis of the grasses made by Dr. Darlington, of Pennsylvania, in which he gives the first rank in point of nutriment to the Kentucky blue grass. Next in order he places what we call timothy, but in New York, and east of it, it is called herds-grass. This is certainly one of our most valuable grasses. None is more certain to vegetate when the seeds are good, and proper care is taken in the preparation of the land, nor is there any that comes to a more speedy maturity. If sowed in the fall, say in September, on good land, it commonly produces a good crop the next season. It may also be sown in the spring, but then it will not produce a crop until the next July twelve months. There

is however some economy in this, for an intermediate crop of oats may be taken from the same land. But the spring sowing, especially if the summer should be hot and dry, I have more than once found a precarious dependence. The fall sowing is upon the whole rather to be relied on.

Herds-grass, called red top at the north, is slower in its growth. It requires a longer time than timothy in taking a firm hold on the land, but when once well set is more hardy, and will ultimately dislodge it. It may also be sown in lower and wetter land, and will maintain a longer struggle with blue grass, broom straw, and other pests. My practice has therefore been to sow a mixture of these two grasses, say two-thirds in measure of timothy to one-third of herds-grass. The result is, that at first the timothy, being most rapid in growth, is the prevailing crop; in the second year, the two crops are about equally balanced; but in the third year, the herds-grass greatly prevails. Until I saw the analysis alluded to above, I was in the habit of considering herds-grass as valuable or even more so than timothy. You may imagine my surprise, then, when I saw my favorite placed *seventh* in order. This shows how little dependence is to be placed on mere appearances, and how necessary science is to correct our false impressions.

Another grass, to which Dr. Darlington gives a high rank, placing it third in order, is called the orchard grass. This grass is principally valuable on two accounts. First, it grows well on high and even light lands. I once saw a fine crop of it on a gravelly hill-side, and the proprietor told me that it was ten days in advance of his lucerne, so that it furnished the earliest green food for his cattle. And, second, it is certainly the very best grass to intermix with clover, both coming to maturity and both requiring harvesting about the same time; whereas clover is three or four weeks in advance of timothy or herds-grass.

There is still another grass, which in a treatise of this kind ought not to be entirely overlooked, called the Peruvian or highland meadow oat. It grows to a great height, the seed are very abundant, and the product a very prolific one; but the hay is coarse, and generally not much relished by stock. Of this and a great many other grasses I shall say nothing more, because, although valuable on many accounts, they are so inferior to those enumerated above, that I cannot advise their cultivation. I have now dwelt long, perhaps too long, on the first branch of my subject. I need scarcely inform the reader that I am very much opposed to long speeches or long sermons, and equally opposed to long essays. But really I cannot see any thing in the above which ought to be retrenched. I proceed therefore to consider,

Secondly, The peculiar culture which experience shows is best adapted to success in the grass crop. And here the first thing which claims our attention is the most suitable situation. In general, low and moist lands, such as swamps and marshes, and the sides of streams of water, after being well drained, are selected for timothy, and especially for herds-grass. There is no doubt that, with a favorable season, these crops are very abundant in such situations. But there is another which is still more favorable, and that is, where a stream of water may be conducted along a slope, from which frequent little rills may be drawn off, so as to irrigate the whole. In such a situation we may almost bid defiance to the season. It is a fact, well known to every observer, that these crops grow more in the month of June than in all the year besides. It is also well known, that at the time of heading they require a good deal of rain. If, therefore, June happen to be a dry month, the crop must necessarily be curtailed. Hence the great advantage of irrigation.

But, besides these low situations, I have known heavy crops of these grasses to be taken from high lands. If, in fact, the land be tolerably level, rich, well prepared, abounding so much with clay as to form a loam, I would not hesitate to sow timothy, herds-grass, clover, orchard grass, or the Peruvian oats, any where. I have been cultivating the most of these grasses for the last fourteen years. I have had them in every variety of situation, and, with the exception of one year only, I have never failed in having a tolerable crop.

The next thing to be considered is the necessary preparation of the land. And here (if I may be allowed the expression) no crop so peremptorily insists on good treatment as the grass crop. Without good land and good preparation, the labor, and time, and seed are all thrown away. With good management the reward is liberal; but without it there is no reward, but in lieu a positive loss. If therefore the situation be high, and consequently requires no draining, all you have to do is, by frequent ploughings and harrowings, to reduce the land to the finest tilth. Nor let any one feel that he has fully done this, until his whole preparation is made to resemble a square in his garden, well spaded and nicely raked over. If the situation be low, and the water inclined to stagnate, the first and most important thing is to drain it; for of all enemies to the artificial grasses stagnant waters are the most pernicious. In a general treatise, like this, it is impossible to lay down any set of rules that may be appropriate to every particular case. To do this, one must first view the spot and mark its locality. But, as a general rule, there must be an open ditch, proportioned in its depth and width to the quantity of water to be passed off. And although there is great symmetry and beauty in a *straight* ditch, still I would, if necessary, sacrifice these to practical utility. I would therefore conduct the ditch along the *lowest* places, though in doing so it should be somewhat crooked. Into this open and main ditch, all the water should be conducted by drains, or other small ditches, until the whole is drawn off. And here, for reasons which, I take it, are obvious to every one, I would strongly recommend *under-drains*, in all instances where suitable materials can be commanded. I have in my time made many miles of under-drains, but having no stones or other durable materials, in three or four years my drains became stopped up, and therefore useless. At present, therefore, I am compelled to resort to surface draining, a process with which I am by no means pleased; for, besides being a slovenly affair, it is attended with the loss of much valuable land. Draining, however, must be done, and in effecting it every one must be left to his own convenience and taste.

The water being now removed, the next thing is to plough and harrow until the whole is thoroughly pulverized. How often these implements ought to be used will depend on circumstances.

Three times I generally find to be sufficient. But in these low situations, I could never yet dispense with *beds*. Water furrows I have found absolutely necessary to collect the water, from which it is drawn off by means of cross drains. We will now suppose that every thing is prepared as stated above, the water drawn off, the land bedded and in fine tilth: the next thing is to sow the seeds. The best time for this, as I think, is from the middle of September to the middle of October. For this purpose a careful hand ought to be employed, who will scatter the seeds evenly and equally over the whole surface, giving to each spot its due proportion. A calm time must therefore be selected, for if there be much wind, many of the seeds will be wafted away, and the evenness of the crop destroyed. I have already stated that I prefer a mixture of timothy and herds-grass seed, and I have given the proportions. Of this mixture, I consider a half bushel as sufficient on good and well-prepared land, and if the land is not good and well-prepared, even twenty bushels nor any other quantity is enough. And whilst upon the subject of sowing, allow me to say, that two quarts of clover seed, or a bushel of orchard grass or Peruvian oat, is about the proper quantity to the acre. I take it for granted, that no one will understand me as advising to sow *clover* in the fall. These seeds are usually sown with small grain, with wheat or rye in February, or with oats in early spring. The seeds being now sown, other important parts of the work remain to be done. The first is to pass a heavy roller over the whole, then to clean out the water furrows and the drains, and lastly, if possible, to give your meadow a top-dressing of good manure.

But some one will say, if I am to have all this trouble and expense, then the hay crop will be like the Indian's gun, "cost more than it comes to." But let us try this a little. I think the hay crop the very cheapest we can raise. The outlay, I acknowledge, is very heavy; but it ought to be recollected that we are laying the foundation not for *one* crop only, but for at least three, and sometimes as many as six. But we will content ourselves with the lowest number. Now to procure these three crops, we plough and harrow three times, and we roll and manure once. But in getting three crops of wheat, how often do we have to plough and harrow? At least *six* times, and each crop ought to have its rolling, and would be much better if it had its manuring. Three grass crops, therefore, are produced with one half the labor and with one third the expense in manuring. But let us try it in comparison with the corn crop. And if any one gets a corn crop, including the preparation of the land, with less than four ploughings and two harrowings, besides other work with the hoe and cultivator, then he has a mode of doing business of which I confess myself ignorant. To get three crops of corn, therefore, we must plough *twelve* times, and harrow six times, besides doing other labor. Which, then, is the most laborious crop?

But in a discussion of this kind, other things are involved besides the actual amount of labor; for if the increased labor produces a proportionable increase of profit, then things remain just where they were. If I labor more I get more for it; and if I labor less, my profits are proportionably curtailed. Let us test this matter also. An acre of land, such as I have described, will ordinarily produce 3000 lbs. of hay, oftener more than less, but we will fix on that as our standard. An acre in wheat scarcely ever exceeds 20 bushels, generally falls below it; and an acre in corn generally falls short of 8 barrels. But we will fix on these two numbers as the standard. Hay in my neighborhood and in the vicinity of market towns generally is worth $1 per 100 lbs.; wheat in the same circumstances is worth $1 15 per bushel, and corn $3 per barrel. If either be remote from market, the profit is diminished in proportion to the expense of transportation. According to this, the acre in grass, with its three crops, will produce $90; the acre in wheat, with its three crops, will produce $69; and the acre in corn $72. But here is an important fact to take into the estimate, that the $69 for wheat has cost me twice the amount in labor, or the $72 for corn four times the amount of labor, as the $90 for hay did. The result is that less labor has produced the most money. Ought any one then to be alarmed in putting down his lands in grass?

But there is another important item which ought to come into this calculation: which crop, continued for three years, is least injurious to land? Now I will not assume, as many others have done, that the cultivation of the grasses, so far from being injurious, is actually beneficial to the land. I will admit that grass, with every thing else when the product is removed, is an exhauster. But I believe that it has never yet entered into any man's head that grass exhausts as much, or any thing like as much, as corn or wheat. If then grass, with one half or one fourth the labor, will produce much more money, and at the same time exhaust the land much less, then, as an act of sound economy, I must stick to the grass.

But I am tired of writing, and I doubt not the reader is tired also; but I feel that this treatise would be unpardonably incomplete were I to say nothing as to the proper time and mode of harvesting the grass crop. This is a matter of much more importance than farmers are generally aware of; for on it depends the flavor, the nutriment, and therefore the whole value of the crop. And here I shall perhaps advance some things which may be controverted by others. My observation may come in conflict with theirs. But all I have to ask is, "give me a fair trial before you hang me." I say then, in general, that our grasses are allowed to stand too long in the field before they are cut, and that they are allowed to remain there too long before they are carried to the mow. The proper time to mow the clover is when the blossoms *begin* to change from the red to the brown state. The stems and leaves have then come to full maturity, containing all their sugary and other nutritious properties, and the after process is merely employed in ripening the seed. Unless harvested now, the stems lose their juices and become hard, and the probability is, that in curing, most of the blossoms and many of the leaves will drop off, and instead of that sweet, fragrant substance, which alone deserves the name of clover hay, you will have only a parcel of dry, black sticks. The other grasses ought all to be mowed as soon as they have dropped their bloom. Indeed, when the crop is a large one,

a beginning ought to be made whilst they are yet in bloom; for, unless the force is a large one, and the season favorable, some will be advanced too far before it falls under the scythe.

As a general rule, no grass ought to be mowed whilst it is wet. Even a dew will injure it, and a shower of rain much more; nor ought it, if possible to prevent it, ever to get wet after it is mowed. The best plan is, to stir the grass as little as possible. In good weather, there is no need of disturbing the swaths, but let them lie for a few hours, until the top is wilted, then throw them into the wind-row, taking care in doing so to bring the bottom to the top, and it is surprising how soon the whole mass will be cured. I have several times had grass cut in the morning and before night it was under the shelter. In bad weather, this is a difficult crop to manage. In this event, all that we can do is by shocking to protect it from the wet as far as possible. My rule is to have as little in the field as possible. When therefore we begin the harvest, as soon as any portion is fit to put away, it is immediately deposited under the shelter, and after this we cut only as fast as we can take care of it. If therefore a rainy season should occur, no large amount is in the field, and no great loss can ensue. In good weather the process is a simple and beautiful one. A certain number of hands are employed in mowing. These are followed by another set who wind-row the grass, or pile it up as soon as cured; and these are succeeded by a third set, who carry it to the stack or shelter. Thus the whole process of cutting, curing and storing away, goes on at the same time. But the quantity cut should always be regulated by our means to take care of it.

EXTRACTS FROM THE PROCEEDINGS OF THE WENTHAM (ENG.) FARMERS' CLUB.*

At the following meeting, the subject was, "On the application of nitrate of soda, and its effects as a manure." The member introducing it, related the following experiment he had made as applied to wheat:—

"March the 12th, 1840.—Sowed nitrate of soda at half a cwt. per acre on about half a field—missed two stetches, then sowed the remainder of the field with a cwt. per acre. On the 23d of May, the land sown with the half cwt. only was again sown with half a cwt. per acre more, excepting one stetch, still leaving the two stetches without any; in a few days a great difference was perceptible, both in color and strength of the wheat between the land sown with nitrate and that not sown; and there was also an evident difference in the stetch sown with half a cwt. only, being much paler in color, and not so strong in plant as the land sown with the cwt. per acre—and so continued till harvest. At harvest, measured one-third of an acre from the two stetches left unsown, and the same quantity from two sown stetches adjoining; each crop was harvested and thrashed separately, and the result was, an increase at the rate of five bushels and seven pints of wheat, and two and a half cwt. of straw per acre on the nitrated part above that not nitrated. This experiment was made on light land, a pea stubble mucked for the wheat, which lost the color very much in the dry month of April, and became very weak in plant previous to the nitrate being applied, but improved very rapidly afterwards."

He had also applied it to barley and oats, without receiving much benefit, and is of opinion that applying it to land of a deep staple and already in a good state, likely to be injurious, by producing too luxuriant a growth of straw, and tending to injure the quality of the grain without increasing the quantity. In corroboration of this, another member related an experiment he had made on a good mixed soil for wheat, in which the crop on the land not sown with nitrate exceeded that which was sown by six bushels per acre, the land all treated alike previously; there was also less straw, (a circumstance not easily accounted for) and the wheat not so good in quality on the nitrated part of the field. Several other statements were made, in which its application had been attended with success, on lands varying from a poor light soil to a strong clay; in an experiment on the former description of land, the increase was at the rate of sixteen per cent., and in another, on a clay soil, an increase of about fourteen per cent. was obtained—the straw on the nitrated part was also six inches longer than where not nitrated. Instances of its successful application to clover layers, and also to grass lands were stated; in the latter case, stock were found afterwards to eat down the coarse places where it had been applied. The following resolution was adopted:—

> Resolved—"That on lands to which it is applicable, nitrate of soda has the effect of stimulating the plant, by which means more straw and an increased quantity of corn have almost invariably been obtained. From the statements made, the wheat crop appears to derive most benefit; but on rich soils, and those in a high state of cultivation, its application has been found injurious to the quality of the grain, and the quantity not increased. It is therefore the opinion of the meeting that strong clay and light soils are the most adapted for its use." * * * *

"The proper application of farm-yard manure, with regard to those crops to which it can be most beneficially applied," was the next subject which engaged attention. The member introducing it, after observing the great importance attending a judicious use of animal manures, and that much would at all times depend on the nature of the soil to which it was applied, contended, that on strong and mixed soil lands it was most essential to apply manure extensively for the root and bean crops;

* The papers from which the following extracts are made offer an excellent example to all agricultural societies. The report of proceedings is but the substance of *farmers' conversations*. Such verbal discussions, conducted with due preparation and order, by the members of any agricultural society, or farmers' club, and the results reported, would alone serve to change even one of the most useless bodies of the kind to the most interesting and useful. We have often, and in vain, urged the commencement in Virginia of this easy and agreeable plan of collecting and diffusing the opinions and experience of farmers.—Ed. F. R.

and as regards the latter, this system had the effect of benefiting the following crop of wheat on lands of that description. On light soils, it was considered decidedly preferable to be applied immediately to the wheat crop, and only a small portion for roots, as it was believed on such lands a heavy manuring for wheat was in some measure beneficial to the succeeding crop of turnips.

Manuring young layers* was often hazardous, and not recommended as a system desirable to be adopted to any extent, except on good lands, as when applied on lighter soils it was frequently found to be productive of little or no benefit in a dry summer.

One member who preferred carrying his manure for wheat, considered it desirable to be applied immediately after the hay crop is carted, as manuring thus early tended materially to strengthen the flag, but an objection (of much importance to a flock farm) was raised to this practice, as sheep would not readily eat the herbage afterwards. On this subject the meeting came to the following resolution :—

> Resolved—"Although no fixed plan can be laid down as to which are the most suitable crops for applying farm-yard manure, a great deal always depending on seasons and the nature of the soil; but from the remarks made, however, the meeting is of opinion that on good mixed soil and heavy lands it is highly desirable to manure well for the root and bean crops; but that on lighter soils, and where it is not considered right to manure extensively for roots, most benefit will arise by applying it immediately to the wheat crop rather than to maiden layers, which latter system the meeting does not consider it desirable to adopt, except on lands of good quality and kind for clover."† * * * *

The following meeting was engaged in a discussion on "subsoil ploughing with regard to its utility and practical effects." This subject, as recommended in the report of the preceding year, now came under the notice of the club, for reconsideration. The member who brought it forward observed, that the opinion he entertained at the former discussion of the question was not confirmed by the practical results he had witnessed during the eighteen months which had elapsed since this subject was before the club, as where he had used the subsoil plough the crops were not improved, neither had the deep-rooted weeds been eradicated as he had anticipated; the only benefit he had derived, was by getting rid of the surface water sooner, from the easier access given it to escape to the drains.

Another member, occupying mixed soil and very light land, had subsoiled his entire farm as it came for fallow, leaving a small portion in each field unsubsoiled, but without perceiving any decided advantage, excepting that where he has subsoiled there is less labor in ploughing than before. Other instances were given, where the subsoil plough had been used, without any beneficial effects being perceptible; one case only was mentioned in which it had proved of any advantage; on a piece of pasture land recently brought into cultivation, and previously drained and subsoiled, it had been attended with success, although it was inferred that the draining as well as the subsoiling tended to produce this result. The disappointment of members was general, as it was believed to be of no use where the subsoil is of a sterile nature, but requiring a greater quantity of manure to render it productive, fully proving that on lands where it has answered, a better soil was in some measure brought into action than before. The following resolution was ultimately passed, still leaving the question open for any light which may eventually be thrown upon it.

> Resolved—"As far as the experiments have gone in this neighborhood, no pecuniary advantage has resulted from the use of the subsoil plough; at the same time, the meeting does not consider itself possessed of sufficient information to come to a satisfactory decision on the subject."

"The breed of cattle best adapted for grazing purposes," was a subject occupying the attention of the club in September. The member introducing it having had many years' experience in grazing Scotch, Devon, and short-horn bullocks, at one time was in the habit of grazing the former kind, but considers the beasts now obtained from Scotland to be generally of an inferior description; they must also be bought at a higher rate than others. A well-bred Devon is a good beast for grazing, but he prefers the short-horn breed to either of the above kinds, as he has generally found them to make more growth, and also to possess superior fattening properties. The consumption of food by a short-horn was undoubtedly greater than that of a Scot, but the increase obtained in size and weight by the former fully compensated for the extra food consumed. In a trial made by another member between these two breeds, it was ascertained that the short-horns consumed five bushels of turnips per day, and the Scots but three; the short-horns, however, grazed decidedly the fattest, so that there was but little difference in the end. Herefords were noticed as possessing much disposition to fatten, but of these there was not sufficient experience to judge, as they are not much grazed in this neighborhood. The meeting adopted the following resolution :—

---

* Recently sown grass-lands.—Ed. F. R.

† While presenting this opinion of practical farmers, we must protest against its soundness, at least for this country. Experience and observation have concurred with reasoning to convince us that it is better to apply manure as top-dressing to grass (clover) than to grain crops, and the more so as it is the less rotted or reduced. And though knowing but little of root culture, we should deem it far better to give to roots, and all succulent crops, manure in proper condition for their use, than the same to the grain crops; the latter kind being, in general, the last on the farm to which we would advise the applying the farm-yard manure, if the application to grass and to roots, vines or pea crops, were as convenient. Manure increases the stalk and leaf, and the tuberous roots of plants more than their seeds; and therefore should be given especially to those crops of which it is desired to increase the general bulk, and not to those of which the seeds alone are the important or sole object of product.—Ed. F. R.

Resolved—"That the short-horn breed of cattle is the most approved for grazing purposes, from the circumstances of their making more growth, and also possessing greater fattening properties than the other kinds; and although found to consume more food, this has generally been compensated for by their fattening in a shorter period."

The following meeting was engaged in a discussion on "The breed of sheep best adapted to this district, combining weight and quality of fleece with aptitude to fatten." The member bringing this subject before the club contended that, for all purposes, the pure Southdown breed was in every respect to be preferred. As regards a cross, that between the Down and Leicester was undoubtedly the best, but not equal to the pure breed of the former. The quality of the mutton of Down sheep was superior to that of any other breed (the Norfolk excepted), and generally obtained the highest price in Smithfield market; he believed they would make a better return to the grazier, and instanced a case of Downs and half-bred Leicesters having been bought from the same flock and kept together; the Downs beating the Leicester considerably. He thought there had not been that attention paid to the improvement of the breed of Southdowns which there had been to that of the improved Leicesters. Crosses between the Norfolk and Southdown, and between the Norfolk and Leicester, were also noticed, but not considered equal to the pure Southdown, requiring longer time to fatten, and when fat not so saleable as the latter. The Down wool was equal in quality to any other, and if kept well, will clip nearly as much as a cross-bred sheep.

On the other hand, it was contended that there was no breed of sheep, for grazing purposes, better suited to this district, particularly where early maturity is an object, than the first cross between the Southdown ewe and the Leicester tup, and as both breeds possessed great aptitude to fatten, (the Leicester in the greater degree), the stock obtained from such a cross could not be inferior to either parents. There were some sheep called half-bred Leicesters, but partaking of several crosses, whose fattening properties were greatly inferior to those of the first cross, neither is the mutton so good in quality. It was also argued that Downs require more time, and although it was allowed they possessed more hardihood than half-bred sheep, and can be kept to more advantage in greater quantities, still they would never produce so much weight of wool; and as sheep in this neighborhood are generally returned at from twelve to fifteen months old, and many are often sold in the wool, there were none so suited for these purposes as the latter breed. An animated discussion took place on this subject, occupying this and part of a subsequent evening, which ended in the adoption of the following resolution:—

Resolved—"That for the purposes of a breeding flock, the pure Southdown is the best; and that for grazing and where early maturity is an object, the first cross between the pure Southdown and pure Leicester is the most desirable, as possessing more aptitude to fatten, and producing greater weight of fleece; but where a large quantity are kept and a longer time allowed for fattening, there is no better description of sheep than the pure Southdown." * * *

[*From Isle of Thanet Farmers' Club.*]

A discussion took place respecting turnips, when the general opinion expressed was, "That manuring immediately before the seed is sown, will produce a better crop than dunging the land in the winter; and that drilling Swede turnip seed at ten furrows to the rod, and other turnips at twelve or thirteen furrows, is the preferable method."

The subject for discussion on the 5th of January was, "The best time for cropping the land." There were only seven members present, one of whom stated, "That to his knowledge some barley sown in January, was better when harvested than that sown in March, the same year." Another stated, "That he knew barley sown in February, better than that sown in April." The following resolution was unanimously agreed to:—

"That all spring corn shall be sown as early as possible, provided that the ground is in a proper state to receive it." * * *

At the meeting on the 9th of March, on the subject of "making manure," it was contended by some members, "That it is best to allow the animals that are fatting to go loose in the farm-yard." It was also contended, "That it is a good plan to keep a sufficient number of bullocks tied up fatting, and have others loose in the yard, ready to take the place of the fat ones as they go off." The following resolution was agreed to:—

"That it is the opinion of this Club, that to make the most and best manure in the yard, is to feed beasts with Swede turnips and oil cake, with cut hay and straw, about a quarter part of the latter, to exclude as much superfluous water as possible, allowing the animals to run loose."

FACTS ON FOOD AND MANURE.

From Squarey's Treatise on Agricultural Chemistry.

"It has been before stated that every part of a plant contains nitrogen as well as carbon; but, as an invariable rule, the seed of all plants contains a much larger quantity of nitrogen than the leaves and stalks, and a lesser quantity of carbon, and inversely, the leaves and stalks contain a much greater quantity of carbon, and a lesser quantity of nitrogen. Now when a horse is fed on grass, his food consists almost entirely of carbon; and the result is, that when he has a sufficient supply he gets fat—that is, that particles of oily, fatty matter are deposited on the muscles under the skin; but, as it is well known, a horse in this condition is quite unequal to any work, and the least exertion reduces his bulk. But when the same horse, under other circumstances, is fed on corn, his food consists principally of nitrogen; and although he may, never, under this keep, get as fat as under the other, still the increase he does acquire will be pure muscle, or, as it is technically called, sound flesh; and on this keep he can perform infinitely more work with less fatigue than on food containing no nitrogen.

"A more complete instance could not be ad-

duced to show that animals as well as plants can only assimilate that food which is presented them; in the first case, carbonaceous matters being the food of the horse, carbon is deposited in the shape of fat; in the latter, when more nitrogen enters into the composition of his food, the deposite of muscle preponderates. So it is with wheat. With a manure that only supplies carbonaceous matter, starch is the result. With a manure containing nitrogen, gluten is formed; both cases being completely analogous, and affording unerring proof of one simple and uniform law."

Another example of the singular effects resulting from the use of a chemical manure; not in the common and well known case, resulting from all manures, of an increase in the quantity of the crop, but in the quality. The authority is Professor Daubeny, of Oxford.

"In an analysis of one hundred parts of two different specimens of wheat which were grown on the same field, one of which had been dressed with the nitrate of soda and the other not, the result was—

Wheat on which nitrate was used, gave	
Bran	25
Gluten	23½
Starch	49½
Albumen	1¼
Extract, loss and water	1
	100
Wheat on which no nitrate was used, gave	
Bran	24
Gluten	19
Starch	55½
Albumen	1¾
Extract, loss and water	¾
	100"

Thus it is seen that the wheat so nitrated contains four and a half per cent. more gluten and one half per cent. more albumen than the wheat not nitrated; and as it has been stated that gluten is the substance to which flour owes its nutritious qualities, this alone would prove our position. But if we carry our investigation further, and see its results as to the real produce of bread, we shall be more fully convinced than ever of the utility of this manure. And here again we resort to experiments made by the same distinguished professor, for an elucidation of the fact.

"Three pounds and a half of flour made from wheat dressed with nitrates produced 4 lbs. 14 oz. of bread; whilst three and a half pounds of flour, made from wheat where no nitrate was used, yielded only 4 lbs. 4 oz. of bread; thus leaving 10 ounces of bread in favor of the wheat so nitrated."

THE FARM AND FARMING OF THE REV. J. H. TURNER.—NO. I.

To the Editor of the Farmers' Register.

In the last (February) number of the Farmers' Register, I am personally called on by my highly respected friend, Dr. Dupuy, for a general detail of my mode of farming. This call is also seconded by the worthy editor himself. Being thus publicly and respectfully called on, I do not feel at liberty to refuse. On the other hand, I promptly and cheerfully comply, and, in my turn, I call on the doctor, and hope that you and he will call on other successful farmers to imitate my example.

Indeed, I have long thought that this is one of the very best modes to diffuse practical agricultural information among the people. We now have several very valuable agricultural periodicals circulating in our country; and I have no doubt that the very best expedient for increasing their circulation and usefulness is, for practical farmers generally to do just what I am called on to do at this time. It is true, and I must in justice to myself state the fact, that I do feel a great reluctance in presenting myself in the prominent attitude which I must necessarily assume in such a communication. Were I to consult inclination alone, I would certainly still occupy the same quiet retirement I have hitherto enjoyed. But my friend, the doctor, intimates, very truly, that there is no free-masonry among farmers. If they have any thing that is valuable, whether it be animal, seed, implement, or information, they are very willing to share the benefits of it with their fellow farmers. The only difficulty is to bring them to the pen. They will *talk* by the hour, or even the day, but to *write* is a labor from which they insist to be excused. I, in common with them, have this same feeling; and with me it is so strong, that it requires no little effort to shake it off. But I will try, and if I can be of any service to this good cause, and especially if I can call out the doctor and other judicious farmers in the same way, I shall feel that I have accomplished a great and good work.

With these remarks, I shall at once proceed to the thing in hand. And here I will not, through false modesty, disguise the fact that I have been successful in farming. This success, under GOD, I mainly ascribe to two things. The first is, that from the beginning, I endeavored carefully to avoid the faults, or mistakes, if you please, into which I clearly saw that many others had fallen. And the second is, that I was careful to avail myself of all the local advantages which my peculiar situation afforded.

Under the first head I will mention, as a palpable fault, I may even call it the crying and ruinous sin of farming, the great, the excessive quantities of land that many are anxious to encumber themselves with. I call all that land *excessive*, and even worse than useless, which the owner cannot turn to a profitable account. When, therefore, a man has as much land as he can cultivate well, furnishing as many shifts as an improving mode of farming requires, and besides this, as much in woods as will supply materials for his enclosures and fuel, all besides is a mere expense without any profit. I could now, did it not seem invidious, point to many splendid estates, which, so far from paying a fair profit, do not yield two per cent. on the original cost and fixtures; nay, some, I verily believe, bring the proprietors in debt every year. And what can be the reason of this? It is not because there is not space enough to operate on, it is not because the lands are so poor as to be absolutely unproductive, nor is it because there is not sufficient force to cultivate them; but it is simply because there is more capital involved than can be turned to a profitable account. I mean that the land, the labor, the stock, and the neces-

sary fixtures have altogether amounted to a sum on which the products can pay nothing. This, therefore, must necessarily be a losing concern.

Besides, these overgrown estates require every thing on a corresponding scale. The house, the stables, the garden, the pleasure grounds, the dinings must all be large. But these large things cannot be called into existence for nothing; nor can they be continued for nothing. Large establishments always demand large expenditures. Whilst therefore the income is large, the outgo is still larger. And hence it is that these great estates have often changed hands in less than three generations.

Another great error into which many farmers fall is, that they undertake more than they can accomplish. They plant more than they can cultivate. The consequence is, that the ground being badly prepared, and the culture defective, the crop must necessarily be a poor one. I have no doubt that the same manure and less than half the labor, expended on a few acres, would often produce more than the whole farm, cultivated as it now is.

Connected with this I will mention, that many farmers keep more servants and more stock than they can employ in a profitable way. The master must have his body servant to brush his coat, and his groom to saddle his horse; and the mistress must have her maid to do up her caps, and her house-keeper to carry her keys; and then, jointly, they must have their carriage-driver, and footman, and butler, and dining-room servant, and nurse for every child, and laundresses, and meat-cooks, and pastry cooks, and scullions, and head gardener, and under gardener, and I know not how many domestics besides, and all these with one or more apprentices under them. Then there must be the saddle horses, and carriage horses, and the bob-tail ponies for young master and young mistress to ride. Now all this looks very well on paper; but the question is, who can support it? Or if things do not proceed to the extreme stated above, it is a well-known fact, that farmers do generally keep more servants, and more horses, and more dogs, and other mere matters of pleasure, than they have any use for.

Now I had observed these and other kindred faults, and, when I became a farmer, I determined to avoid them; and reared as I was to habits of labor and economy, I found no great difficulty in doing so. My first purchase was therefore a very small one. I bought just so much land as I thought, with my means, I could bring speedily into profitable cultivation. The capital so far invested was a small one; nor did it require any great outlay in ditching, inclosing, manuring, labor, and every thing else necessary to use. I however made a great many mistakes, which subsequent experience enabled me to correct. One I will mention. In preparing for my little corn crop, I applied my manure in the drill, and not broadcast. This will do where the crop is corn, and corn alone, but will not do when it is to be followed by subsequent crops. I saw my mistake, and never afterwards repeated it. This plan of spreading a little manure or a little labor over a large surface cannot be too strongly reprehended. It is mere waste; whereas, if it be confined to proper limits, we at once derive the benefits of it.

I ought to mention, that at the time alluded to above, I was engaged in other business in town. This I regarded as my main pursuit, whilst the farm was resorted to for amusement. I had fancied to myself, that after spending a sultry day in town, it would be very pleasant to resort to my country establishment in the afternoon, and there regale my senses with the beautiful fields and fragrant flowers. But I soon found that a farm, even a *small* one, will not suffer itself to be treated as a *plaything*. Do what you will, it will maintain its solid importance—*it will fill your pocket or empty it.*

I must also mention, that the interest which I took in my farm was of a constantly increasing character. In fact, it soon took such a strong hold upon my thoughts and affections, that I was rendered unfit for any other pursuit. The other business, therefore, in which I was engaged, became intolerably irksome. I began it late, and I despatched it as rapidly as possible. I was now engaged in two pursuits, the one was a mere drudgery, the other was my delight. It will create no surprise then when I state, that I soon shook off my town employment, and gave myself wholly to the delights of the farm. Instead of short mornings and afternoons, I now spent whole days in my darling pursuits.

But it would be tedious to detail the various sources of new enjoyment which now presented themselves to me. If I planted a seed, I wished to witness its earliest vegetation; and if I set out a shrub or plant, I wished to inhale the first fragrance of the opening flower. I even thought the shade of my own tree, or the draught of water from my own well, more cooling and refreshing than any other. And I am sure that I never enjoyed the exquisite relish of fruit in all its perfection, until I plucked it from the tree of my own planting.

But before I quit the subject of these pleasure farms, I think it proper to say a little more about them. The impression, I know, is very general among the good citizens of our towns, that such establishments may be resorted to as places of mere pleasure. They figure to themselves a pretty white cottage, with green window shutters, in the very midst of neatness and beauty itself. Here are shrubs, and flowers, and odoriferous plants; and here every thing is beautiful and sweet and fragrant. Then this earthly paradise is so located, that a ride or walk of an hour will carry the fortunate proprietor to his business in town. Oh! how delightful to place wife and children in this beautiful spot during the sultry months of summer? I admit that in one event, and one only, it would be so, and that is where a large property has already been acquired, or where the present business is so lucrative as to sustain the expense. Without this, such a place is a mere moth; it is a constant and rapid drain upon the former or present earnings. It is then the very last thing in which the man of moderate circumstances ought to think of indulging. In fact, I know no instance in which this *double* business has succeeded. One establishment is invariably a drain upon the other.

But whilst I say this, my experience warrants me in adding, that the man of industrious and persevering habits, may so succeed on his small farm, as to justify him in giving up his town business. Accordingly, when I was drawn to the

country, I made farming my only pursuit. In the course of a few years, I cleared the whole of my first purchase, and so enriched it as to make its cultivation profitable. I then bought more land; and as more labor became necessary I added it also, but always in small quantities at any one time, making it my invariable rule to improve as I proceeded. Thus I continued until, before I was aware, I fell into the common error of farmers: I *got too much land*. A considerable portion of my farm may now be fairly called a garden spot. Just that much I consider profitable, and just that much I ought to own, and no more. The residue, which is too poor or too wet to bring a profitable crop, is a mere incumbrance to my little estate, and I should be better off without it.

Having now detailed certain great evils which I endeavored to avoid—all of which may be summed up in one word—*excess of capital*—I will now advert to certain other things which I thought it of equal importance to *practise*. In this view I would present, as claiming the very first rank, what I would call a system of judicious economy. And here I wish it to be distinctly understood, that by this term I do not mean a niggardly spirit, nor a stinting in any form whatever. I mean that, whilst every body and every thing has a sufficiency, there be nothing wasted. This system I have earnestly endeavored to establish on my farm. In this, I have had to row against wind and tide. There seems to be in the negro an innate propensity to profusion; we see it displayed in his food, in his clothes, and even in the comforts which are exclusively his own, and in all the departments which come under his direction. This propensity, I believe, can never be effectually counteracted; but the injury resulting from it may be in some measure obviated, by the constant vigilance of the master.

But the economy which is ordinarily most profitable on a farm, consists not in mere saving, but in lopping off all useless expenditures. It is in vain to save at one point, whilst a greater loss is sustained at another. I have long been convinced that it is only the speculator or gambler who can make or lose a fortune at a dash. The farmer's wealth never comes to him borne in on the torrent. It is always wafted on the small and gentle rill; and he is the best manager who conducts a great many of these little rills into one general reservoir. The whole machine should therefore be so constructed, and kept in such order, that all the parts may work together. Whilst industry is employed in creating, economy should be equally busy in taking care. In accordance with this, I make it a rule in my little establishment to dispense with every thing that does not in some way or other contribute to our immediate comfort or profit. Every servant and every horse has full employment. I keep no breeding woman nor brood mare. If I want a negro, I buy him already raised to my hand, and if I want a horse or mule I buy him also. Now I will readily admit that it will not do for every body to practise on this Shaker principle; but in my peculiar situation, (of which more hereafter,) I think it cheaper to buy than to raise. At my house, therefore, there are no noisy groups of mischievous young negroes to feed; nor are there any flocks of young horses to maintain.

There is another propensity among our negroes, always annoying, and sometimes attended with considerable loss to the master, and that is a disposition to pilfer. Perhaps there is no farmer, especially among those living near our towns, but is put to more or less inconvenience on this score. In common with others, I have suffered considerably from it, particularly in the loss of my pigs and shoats. It so happened, that if I took a special fancy for any pig, some rogue took an equal fancy for the same; and, somehow or other, he contrived to strengthen his fancy by "the nine points of the law." His fancy thus became stronger than mine, and I was obliged to yield. This inconvenience I resolved to remedy, but the difficulty was to set about it in the right way. After much reflection, I became convinced that my own negroes were the rogues, or that they connived at it in others. The thing could not happen so often without their knowledge or concurrence. Whether, therefore, principals or accessaries, my own negroes were guilty, and the remedy was directed to them. With a view to this, I resolved to take from them all apology for stealing, as far as *necessity* was concerned. I regularly gave to them an ample sufficiency of substantial food—bread without stint, and meat, besides fish, to the amount of four pounds per week. And here let me indulge a passing remark, that of all the hogs I have ever seen, none is to compare to the Berkshire; for besides a fine, round, juicy ham for the master, it furnishes a large fat middling for the negro. And this is precisely the kind of meat which is suited to him. But to return to my expedient. My negroes were also made comfortable as to their clothing and lodging. In addition to these things, which I had reason to believe they would regard as their *rights*, I resolved to allow them other indulgences, which they could but consider as *privileges*. Accordingly, every one is allowed a small piece of good land, which he cultivates as his own. The crop which grows here is the negro's crop, and I exercise no control over it whatever. When the land is broken up for my crop, the negro is allowed time to break up his also; and when my crop is planted or cultivated, his is also; and when mine is gathered, he gathers his, and measures it in my presence, and I commonly become the purchaser. Some persons, I am aware, object to the patching system, alleging that it furnishes facilities for stealing; but managed as above, I cannot think it fairly subject to that objection. On the other hand, good consequences, as I think, result from it. It makes my negro satisfied, and it gives him an interest in his *home* which he cannot otherwise have.

But, besides his patch, I allow to each laboring hand a barrel of corn, or its equivalent in money, and the time of settlement is his great holiday, Christmas. At this time, above all others, our negroes are anxious to have some spending money. Now, by means of this boon, so highly prized by them, I believe that I have succeeded in keeping my negroes perfectly honest for the last four or five years. The practical working of the thing is in this way: if a depredation is committed, *no matter by whom*, my negroes are responsible for it, and double its value is deducted from the Christmas present; or if a tool has been lost, its value is deducted in the same manner. If, however, the thief is given up, and all have an

interest in his detection, the whole responsibility rests on him, and the others are of course exonerated. By this means I also secure my property from the depredations of the neighboring negroes. Thus, a few barrels of corn are made the means of saving my property to perhaps ten times the amount, the whole year; and I am also spared the painful necessity of frequent chastisements. This plan has thus far succeeded so much to my satisfaction, that I determined to state it publicly; and I am very much inclined to the opinion, that were it made general, it would go a great way towards breaking up the whole system of thieving among our servants.

But I have written enough, and perhaps too much, for one paper. From the above it will be seen that, as a foundation for my farming operations, I have endeavored to avoid excessive and injurious outlays in land, negroes, stock, and the other necessary fixtures. The whole may be summed up in this short sentence: The capital involved is as small, as compact, and as available as I could make it. If in the detail I have given to myself a prominency which a becoming modesty would forbid, my plea is, that I have stated the truth, and I could not in candor state less. If this apology is not sufficient, I rely on you, Mr. Editor, and on my good friend, Dr. Dupuy, to supply the deficiency. In my next (for having commenced, I know not when I shall quit,) I propose detailing my plan for enriching my farm.

J. H. Turner.

ORIGIN OF PAPER MONEY.

From Gouge's Journal of Banking.

It is a fact well worthy of notice, that in all countries into which paper money has been introduced, it has owed its origin, not to the demands of commerce, but to the necessities of the state. The reason for this is, that commerce creates its own medium. In commerce, conducted on legitimate principles, mere *promises to pay* are never substituted for actual payment. The merchant may buy much on trust, but when the day arrives on which he has promised to pay, he will, if solvent and honest, fulfil his engagements.

The necessities of the state, in very ancient times, introduced paper money into China, into Tartary, into India, and into Persia. And in modern, or comparatively modern times, the necessities of the state have introduced paper money into Italy, Spain, Portugal, France, Germany, Russia, Sweden, Denmark, Great Britain, the United States, Brazil, and Buenos Ayres.

There are some who suppose, or seem to suppose, that without paper money there would be little or no commerce. We would call their attention to the fact, that in no one country did the necessities of commerce give rise to the use of paper money. The fact is of importance.

The Bank of England was established on condition of lending *all* its capital to government. The first issue of paper money in this country was made by Massachusetts in 1690, not to serve the purposes of commerce, but to satisfy the demands of some clamorous soldiers. The next was made by South Carolina in 1712, to defray the expenses of an expedition against the Tuscaroras. The first of our regularly constituted paper money banks was the Bank of North America. Private scheming was undoubtedly at the bottom of this, but the schemers owed their success entirely to the hopes they held out of relieving by their new institution the pecuniary wants of government. The like is true of the first Bank of the United States.

Banks have, indeed, been established in different countries, solely to aid the operations of commerce. Of this kind were the banks of Hamburg and Amsterdam. But they were *hard money* banks.

PAPER MONEY REFORM.

From the same.

In no country into which paper money has been introduced has the system been reformed. In all, the enormity has gone on increasing, till it has exploded. It was thus with the paper money of China, thus with that issued by Law in France, thus with the assignats, thus with our provincial paper money, thus with our continental money. And thus, we suppose, it must be with the present paper money systems of Great Britain and the United States.

In Austria, France, Portugal, Sweden, Denmark, and perhaps in other countries, as well as Great Britain and the United States, instances have occurred of banks suspending specie payments and afterwards resuming them. But this is, at best, but a partial reform. Banks in which the copartners are exempted from personal responsibility, are chartered monopolies of the most odious description. And whether such banks pay, or refuse to pay, specie on demand, their paper never can adequately perform the *chief* function of money. It may be very convenient as a *commercial medium;* but as a *measure of value* it is one of the most *deceptive* that can possibly be imagined.

ACCIDENTAL EXPERIMENT. RESULTS OF TOP-DRESSING ON CLOVER.

Extract from the Farmers' Cabinet.

On walking over a clover field which had then been mown the second time for seed, and the crop raked into wind-rows, I observed that a square space, about an acre, was much more thickly set, and the leaves of a more vigorous appearance than any other portion of the field, and seeing that the great thickness of the crop was marked with the exactitude of a line, I pointed it out to my friend from a distance, as the work of a bad mower, who had left a part of the crop on the land, not having cut "the bottom half inch;" but on a closer inspection I could perceive that the line ran *across* the swathes, and not *with* them; so that this could not be the cause of the very great difference in the appearance of the crop, which was found to proceed altogether from a closer plant of much more vigorous growth; on which my friend remarked—"The clover-seed with which this field was sown was saved by myself, was carefully cleaned in the barn, and taken

immediately from thence and sown in the field; but my seeds-man scattered it too plentifully at first, and the consequence was, the clean seed was all exhausted and the square which you see was left unsown; but not being willing to leave this portion of the field without a crop, and having no seed at hand, I took the clover-chaff from the barn and scattered it very thickly over the unsown portion of land, thinking there might be a few seeds contained amongst it; and you now see the result, after two crops of far heavier bulk have been removed from the spot before us."

THE POTATO.

From the same.

Mr. Editor—It is perhaps not generally known to the subscribers of the Farmers' Cabinet, that in the potato there are two parts, which, if separated and planted at the same time, one will produce tubers fit for the table eight or ten days earlier than the other. This fact has fallen under my own observation, and is the plan I now pursue in order to obtain an early supply for my table, fine and very mealy. The apex or small end of the potato, which is generally full of eyes, is that part which produces the earliest—the middle or body of the potato produces later, and always large ones. The butt or navel end is worthless, except for feeding stock, and if planted produces very indifferent small ones, and often none at all, the eyes, if any, being imperfectly formed. The potato being cut two weeks before planted, and spread on a floor, that the wounds may heal, separating the small end from the middle, then cutting off the navel or butt, the body or middle of the potato is then divided into two pieces lengthwise, taking care to have always the largest and finest selected, being convinced that if none but large potatoes are planted, large ones will be again produced; small things produce small things again, and therefore no small potatoes should be planted; this practice is too prevalent, and may account for the many varieties and small potatoes met with in our markets. Who would not prefer a large mealy potato to a small one, that will take hours to boil soft, and then may only be fit to feed the cattle with?

For several years past I have adopted the plan of putting potatoes into the ground late in the fall, covering them with manure, sometimes with tanners' waste bark, and always have succeeded in raising a fine early crop. Last fall I had taken up some as fine and large Mercer potatoes as any one could wish; they were covered with tan six inches thick the preceding fall; many weighed sixteen ounces. No particular care or attention was bestowed upon them through the summer, the tan not permitting any weeds to trouble them, or to draw out the nourishment from the earth, they had therefore all the benefit of the soil, kept moist and clean by the tan, for tan will keep the ground moist and clean, and in an improved state, in the driest season. I have found the great advantage of it to my asparagus and strawberry beds, which are annually covered with it.

The potato I consider so valuable and indispensable a vegetable, and having never seen a suggestion in print of separating the potato and planting each by itself,* that I have been induced to send you this imperfect and hastily drawn up communication. Perhaps you may think it worthy a place in the Farmers' Cabinet, and if so, should be pleased to hear that some of its patrons will try the experiment of planting separately each part of the tuber, believing that the potato may be much improved by a due regard to the above suggestions. J. F. H.

Lancaster, February 26, 1842.

MAGNESIAN LIME.

From the same.

At page 276 of vol. v. of the Farmers' Cabinet, in a short extract from the "General Report of Scotland," it is stated that "it had been long known to farmers in the neighborhood of Doncaster, England, that lime made from a certain stone, and applied to land, often injured the crops considerably. Mr. Tenant, in making a set of experiments upon this peculiar calcareous substance, found that it contained magnesia, and on mixing some calcined magnesia with soil, in which he sowed different seeds, he found that they either died or vegetated in a very imperfect manner, and the plants were never healthy; and with great justice and ingenuity he referred the bad effects of this peculiar limestone to the magnesian earth it contained. Yet it is advantageously employed in small quantities, seldom more than 25 or 30 bushels per acre."

Mr. Tenant's account of his experiments first appeared, we believe, in the Philosophical Transactions of England, and we know not that it ever appeared in any other form. It is certainly not in very general circulation. We cannot say, therefore, how extensive, varied and accurate the experiments may have been. But it is from such vague, loose and indefinite accounts as the above, that we are called upon to swallow the whole doctrine and all its consequences—head, horns and all, without making a wry face, and that too in opposition to a host of proofs of its utter fallacy, derived from one of the most extensive and decisive experiments ever made in agriculture.

But leaving Mr. Tenant's account of the matter out of view for the present, let us examine that which the advocates of the doctrine it was intended to support have vouchsafed to give us. They tell us that he mixed *some* calcined magnesia with the soil, (but they do not tell us how much,) and found that seeds sown in it either did not come up at all, or if they did, did not grow vigorously. Well, we grant that they did not. What then? Does it necessarily follow that magnesia is destructive to vegetation? Suppose he had mixed pure lime, or even pounded chalk, with his earth, every body knows, or may easily ascertain, that if an undue proportion of either were used, his plants would have withered and died, the same as they did in the magnesian mixture. Would it not then be just as philosophical to assert that lime was in the latter case injurious to vegetation, as that magnesia was in the former?

Here then appears but a single unvaried expe-

* At p. 132 of the Cabinet, vol. v. our correspondent will find this subject particularly treated.—Ed. Cab.

riment, with an attempt to build a very important theory on the narrowest possible foundation of fact. And never has a hastily formed or unsound theory been more signally overthrown by subsequent experience. Instead, therefore, of saying that it was just and ingenuous to refer the injurious effects of the lime in question to magnesia, we should rather say that it was a hasty and unjust conclusion, and would never have been put forth by one acting under correct views of the requirements of the inductive philosophy.

But it is not against the possibility of the injurious nature of the Doncaster limestone, or of the correctness of Mr. Tenant's experiments, for we care not a straw whether they are correct or otherwise; but it is against the broad doctrine of the deleterious nature of magnesian lime in all its forms, attempted to be deduced from them, that we contend. It is against the senseless repetition of this doctrine, unsupported as it is by any subsequent experiments, by every unfledged agricultural essayist, or every enthusiastic builder of plausible theories, that we enter our protest. Agricultural publications are extending in circulation every day, and are beginning to be looked up to as sources of correct information. It is of importance, therefore, that theories diametrically opposed to every day's experience should not be reiterated in them again and again, without attempts being made to show their utter fallacy. Lime, in some parts of our country, is a very costly article for manure, owing to the expense of carriage. A young farmer in one of these has a poor exhausted farm. He sees in the Cabinet and other publications lime highly recommended as a manure, but he also sees essays professedly written by practical men, wherein it is repeatedly set forth that all magnesian lime is deleterious to vegetation, and that each one whose liming has not answered his expectation, refers his disappointment to this cause. He takes up the reports of the different geological surveys lately made in this country, and learns from them, as well as the pages of the Cabinet, that a very large proportion of the limestones of our country are magnesian, and many of them highly so. Would not such a person probably reason thus:—I am very poor as well as my land. This lime is a very expensive thing. I shall probably get of this bad kind, as I am no judge of the article. I shall lay out my last dollar, and probably make my land even worse than it now is. Would he be likely to lime under such views? Would he not more probably toil on from year to year as poor as he began—still afraid to apply the great renovator to his soil? To such, however, we would repeat, what we have already said, that all the benefit which has been derived from lime as a manure, to Pennsylvania and to a great part of New Jersey and Delaware, has been derived from magnesian lime. This is fact and experience; the other is but theory based on a narrow foundation. Then let not this bug-bear of magnesian lime, set up by those who seem to be profoundly ignorant of what is passing around them, deter you from following the bright example set you by the enlightened farmers of south-eastern Pennsylvania. Put on your magnesian lime in such quantities as their experience may have pointed out. Shut your ears against this senseless clamor, and after you have faithfully done your part, trust the rest to the silent, unseen, mysterious operation of those laws which govern the material world, with the full assurance that you will reap a rich reward. S. Lewis.

Dec. 28, 1841.

MAGNESIAN LIME.

From the same.

Mr. Editor,—On reperusing the pages of the back numbers of the Cabinet, a custom to which I confess I am much addicted, I find an article at page 339 of the 5th volume, on "Magnesian lime," which I would wish to notice, for the purpose of drawing from the writer farther information on a topic which still agitates the minds of some of our practical friends, although to him this must appear strange after what he has said to settle the question by a verdict which would seem to admit of no appeal: but as facts are stubborn things, and eye-testimony goes a good way with a class of persons who are accustomed to judge pretty much by the light afforded by that mode of reasoning, I have wrought myself up to the point of encountering from your correspondent a withering glance that may possibly render me incapable from ever looking into the subject again; and yet that would be a pity, for how could such as I come to a knowledge of the truth, if we were to give up one of our seven senses, and consent to be led by the doctors, *seeing*, as we do, that none are more apt to differ than they?

That the presence of magnesia in lime was once believed to be injurious to vegetation, cannot be denied. That it is now by many considered rather advantageous than otherwise that it should contain a certain portion of magnesia, would also appear to be a fact; while others there are who look upon its presence as neither beneficial or hurtful, farther than robbing the lime of just so much *carbonate*—to which state it returns on exposure to the atmosphere—as it is found to contain on analysis. Now which way lies the truth? And after Mr. Kinser has answered this question, I would ask why is it that lime, when quite pure from magnesia, can be applied in almost any quantity to land in almost any state, whether of poverty or fertility, without injury to the crop, while that which contains magnesia, to the amount of about 40 per cent., cannot be used on the same soils and under the same circumstances to a greater extent than, say from 40 to 60 bushels per acre without manifest injury? We are told that in England lime is given with impunity, even to the amount of 500 bushels per acre—what would be the result if such excess were indulged in here with lime containing 40 per cent. of magnesia? It may be said the difference is in the climates of the two countries, but I must be permitted a difference of opinion. In the third volume of the Cabinet, pp. 14, 17, there is recorded a series of experiments, the correctness of which I was informed by the then editor of the Cabinet might be implicitly relied upon, as they had been copied from a diary or journal that had been kept by the writer while in the management of certain estates in Wales, upon which they had been most carefully conducted, for the purpose of ascertaining the value of lime in agriculture,

and where occasions had offered to prove that its application, even to the extent of more than 500 bushels per acre, had been attended with the most beneficial results ; but there the limestone—a pure black marble—contained, by analysis, 98 per cent. of carbonate, with not a trace of magnesia. If the readers of the Cabinet, having the 3d volume, would turn to these pages, I think they would be much interested with a perusal of their contents.

At page 275 of the 4th volume of the Cabinet is a letter on this subject from Mr. Mahlon Kirkbride, of Morrisville, Bucks Co., which shows conclusively—at least to me, who saw and examined the land upon which the lime had been used in the way that he states, and found it comparatively barren, the year after the time when he wrote—that the injury had been caused by the lime, which, it is admitted, contained magnesia in its composition. He says, "my father had a field of 25 acres of as good wheat soil as could be found—a deep loam. Its produce for years stood almost unrivalled ; he, wishing to make it still better, applied to a part 50 bushels of lime to the acre, to the balance (excepting half an acre) about 65 or 70 bushels to the acre ; the result was as follows : in 1837, wheat crop not much more than the seed ; 1838, corn, about 10 bushels per acre on the heaviest limed parts, on the other 40 bushels ; 1839, oats good where there was the least lime, on the other part 15 to 20 bushels per acre. The half-acre above alluded to received 50 bushels, and the result was, of wheat not a handful ; of corn, some stalks three feet high and two bushels of nubbins ; of oats a growth of straw 16 inches high, which refused to show any symptoms of ripening, and was cut to get it out of the way." It must be added, the spot on which the lime had been deposited when taken from the canal-boat, and from whence it had all been removed with the most scrupulous care, had not, three years after, produced a single trace of herbage, not even a weed—would Mr. Kirkbride be pleased to inform us of the *present* state of that portion of his land ? At page 55 of the 5th volume of the Cabinet, notice is taken of Mr. Kirkbride's communication by a writer who has had great experience in the use of lime, and it is to be regretted that he did not give us the analysis of that which he applied so unsparingly and profitably.

Now I am sure I have no private interests to serve, and no prejudices to support, but I would just ask Mr. Kinser, at the risk of having applied to me the old adage, "a fool can ask more questions in an hour than a wise man could answer in a month," 1st, How is it that when the lime from Messrs. Potts and Dager's quarry, containing 96 per cent. of carbonate, and not a particle of magnesia, is exposed in a heap, and has become perfectly slaked, that white-clover and the finest grasses will be found to penetrate through the lime at the margin of the heap from the depth of perhaps an inch or two, and spread over its surface ; and on the removal of the heap, that the herbage will grow on the bald spot and become a rich turf in a short time ? 2d, How is it, that the lime burnt from the stone quarried from the south side of the valley at Downingstown shows exactly the same results ; while that produced from the stone quarried from the north side of the same valley, perhaps not a quarter of a mile distant, is totally different in its effects, destroying all vegetation, and leaving a galled spot for years where it had been deposited for slaking ? for this fact, and a true analysis of these two varieties of limestone, I would appeal to Dr. Sharpless and his brother, who reside on the spot, as also to Mr. Lindley in the immediate neighborhood, asking of the latter gentleman if he has not known oats, sown on a limed soil, to penetrate through a lump of lime several inches in thickness, and grow to the height of about five feet with the greatest luxuriance, *that* lime having been procured from the south side of the valley. The difference between the two stones being peculiar likewise, that from the north side being *heaviest*, but producing the lightest lime—the stone from the south side being lighter, but producing the largest quantity of pure lime ; showing that more foreign matter had been thrown off and dissipated during the process of calcination from the stone obtained from the north side of the valley, and proving conclusively, the greater purity of that from the south side. And 3d, I would ask, was it ever known, that herbage would spring up on the margin of a slaked heap of lime containing 40 per cent. of magnesia, even penetrating through it from the depth of an inch or two, and spreading over it, and for the earth to show no sign of its pernicious effects in the shape of a galled spot, after its removal ?

The subject is of vast importance, and is the cause of my troubling you with this communication, my object being to "keep the ball in motion," and to elicit the truth. And to this end, I would take the liberty to ask your subscribers, Mr. R. T. Potts, Mr. Dager, and their neighbor, Mr. Henderson, who has, I understand, erected a kiln for the purpose of calcining the cuttings of his pure white marble, whether they have it not in their power to throw some light upon the matter, not doubting that the white marble of Mr. H. contains at least as great a proportion of carbonate of lime as the beautifully mottled variety of Potts and Dager, namely, 96 per cent.

That magnesian lime has proved of very great service when applied to the soil, no one can deny, for the evidence is before our eyes ; but I hope that the subject may be investigated to its better understanding, without fear for the result. And I know of no one who has it in his power to do us more service than your correspondent—will he, therefore, take the above remarks into his consideration, and favor us with his conclusions ? I am, I must confess, by no means inclined to *blink* the question, lest it should "arrest the march of improvement, and throw cold water on the spirit for liming" which is abroad in the land, but I do wish that your correspondent would inform us of the cause of the very great difference which is seen in the effects between lime containing 96 per cent. of carbonate and no magnesia, and that containing about 50 per cent. of carbonate and 40 per cent. of magnesia. It may be that magnesia operates in a different manner from lime—nay, it might perhaps be found to be more valuable than it for the purposes of agriculture—and to this I have not the slightest objection ; that is of no consequence, and need not frighten any one whose sole object is to become acquainted with the true mode of its operation.

P. S.—Since writing the above, the No. of the Cabinet for February has reached me, and I find that your correspondent, Mr. Lewis, of Pottsville, has embraced the opinion that the presence of magnesia in lime is not injurious for agricultural purposes, nay, that it is "diametrically opposed to it;" and to this decision he has been brought, not by a "two-penny experiment made in a garden-pot, or the corner of a field," but by its extended use over hundreds of thousands of acres through a long period of years, in opposition to the "would-be oracles of the day," or the theory that has been "babbled," on the subject. Now, by such men as your correspondents, Messrs. Kinser and Lewis, I presume we shall be sure that the subject will be properly treated, and the truth elucidated, but I would meekly ask why do these gentlemen use such strong language to express themselves, if they are not in some way interested in the matter? Surely it does not require such terms of contempt and reproach to silence the workers in a garden-pot or the corner of a field, or these very small oracles or babblers who presume to arise in their path? S.

Luzerne county, February 28, 1842.

REMARKS ON THE OPPOSITE OPINIONS OF MAGNESIAN LIME.

In the Farmers' Cabinet there has been recently revived, and is warmly contested, the old controversy as to the alleged deleterious action of magnesia in lime. Two of the articles are inserted above, which set forth the opposing views. This still doubtful question is one of the many subjects of opprobrium to agricultural science—or rather of chemical science pretended to be applied to agriculture. Chemical writers have been content to repeat, and *merely* theoretical farmers to believe, the opinion of Tenant, announced half a century ago; which opinion, however interesting and important to agriculture, and however true might be the particular experiment on which it rested, was certainly not established generally and fully. Other and varied experiments ought to have been made, both by chemists, and by practical farmers who had it in their power to try and compare the effects of lime from both pure and magnesian limestones. But while the various printed articles of argument, or loose discussion, would have filled a volume, there has not been carried through a single series of judiciously planned and accurately conducted experiments, which, if performed, would have decided all doubts, and removed every obstacle to this all-important branch of improvement in a very large agricultural region.

The fact that magnesian lime in large quantities is injurious or even destructive to vegetation and to productiveness of soil, however certain, is by no means a proof that the application of magnesia (either in its calcined and pure state, or when carbonated and mild,) is hurtful. There are other manures (indeed most others) highly beneficial in proper quantities, which are injurious in excessive quantities. Pure lime itself is adduced by the witnesses on one side to show that it may be applied in any quantity without damage to vegetation, and that benefit is found by increasing the dose to 500 or even 1000 bushels, in the caustic state, at one application. Yet, without undertaking to deny these particular facts, (as we know nothing of the precise conditions of the trials,) it is certain that our liming farmers in lower Virginia find 150 bushels dangerous, and 100 bushels or even less often unsafe. Yet no farmers in our region have made more profitable improvements, except the marlers, than those who have used lime. The kind most generally used by them, and from which all their facts of injury by excess have been derived, is oyster-shell lime, which is pure lime, containing no magnesia or other foreign matter.

Of shell marl, or merely calcareous marl, the principal and almost sole fertilizing ingredient is mild lime or *carbonate* of lime; and when we first commenced its use, we had no idea that any quantity of it could injure land by its excess. Yet a few years' experience showed great injury from applications containing not more than 200 and sometimes less than 150 bushels of the proportion of this mild lime. The richer the marl of course the greater the injury from a heavy dressing. Yet what farmer of common sense would therefore denounce the use of marl as injurious, or would prefer the poor to the rich, because 500 bushels of the poor produced great and continued increased product, while 500 of the rich would produce disease and great injury to the grain crops, for many years?

Theorists have extended the sound objections to caustic magnesia being applied too heavily as manure in newly burnt lime, to the existence of carbonate of magnesia naturally in soils, or in manures; and have inferred that, even in this mild or natural form, it was the cause of sterility. We have no practical knowledge of magnesian soils; but cannot believe that a substance so similar to lime in its chemical qualities can be so different in its operation as manure. Soils may indeed be barren from an excess of magnesia in their natural composition (if there be any such) as others certainly are because of excess of lime; and others by excess of the siliceous and others of the clayey ingredient. But any quantity of magnesia that could possibly be applied as manure,

after it had become carbonated and mild, we cannot believe to be otherwise than an aid to fertility. The bottom lands of the Red river, in Louisiana, have two or three per cent. of carbonate of magnesia, (according to the analysis of a specimen which we examined,) and other celebrated fertile soils also have this earth as an ingredient.

ED. F. R.

SUGAR BEET.

From the Farmers' Cabinet.

Mr. Editor—I find that the Massachusetts Agricultural Society has awarded a premium of $15 to F. Tudor, of Nahant, for a crop of sugar beets measuring 1300 bushels per acre. Mr. Tudor's account of the *management* of the crop—a statement which should, I think, always be made to accompany a premium crop—was as follows. "The ground was old pasture of indifferent soil and very stony; it was broken up in 1840 by trenching, 20 inches deep, which brought much poor soil to the surface. The stones were gathered from the land and buried in the bottom of the trench, upon which was spread three inches deep of mussel-mud, then the turf and the best of the soil, then two inches of rock-weed fresh from the shore, or cut from the rocks; then the less rich part of the soil and more mussel-mud, the top being left with the poorest and most gravelly soil. In the spring of 1840 it was sown with sugar-beet, but the crop was poor. In 1841 the land was ploughed six inches deep without reaching any of the rich soil below, the surface still exhibiting little but yellow loam and gravel. Upon this I caused sugar-beets again to be sown, and when the plants had sprung up, I had the land *dressed on the surface*—merely spreading on 15 cords of rich cow-yard manure. This caused the young plants to shoot and grow away most vigorously, and the crop has been so large that I have determined to exhibit it before the State Agricultural Society, and put in a claim for premium. No particular care has been taken of the crop, for although the seed had missed on several patches, they were not filled with plants, while during the drought of August, many of the tops were cut as fodder for cows; but for this, I believe the crop would have produced 1600 bushels per acre. The crop was sold by auction, and the weight given was what the purchasers paid for. The largest root measured 34 inches in circumference, and weighed 31 pounds, but it was hollow; the largest sound and perfect root weighed 21 pounds; a fair bushel weighing 60 pounds. I think the large crop which has been produced on my land was not caused by the trenching, but *by the looseness of the soil and the top-dressing of rich manure;* the value of a top-dressing in a season of drought being undoubtedly great."

I conclude with one remark—the above account speaks volumes for the system of subsoiling and top-dressing, a mode of management which seems at length to be commanding the notice of agriculturists generally throughout the land.

J. GRANT.

MINUTES OF AGRICULTURAL FACTS.

1. *Green sand and gypsum of James river.*—In the beginning of March we saw for the first time the spot dressed with this manure at Evergreen, which was described at page 645 of vol. ix., and incidentally referred to at page 494, vol. viii. The superiority of fertility of the manured space, as shown both by the remaining stubble of the wheat crop of last year and the young clover, is very manifest, and is fully 50 per cent. over the adjoining ground, though that is very good and productive soil—a fine loam of medium texture, originally rich, and neutral soil, and marled previous to this application, which was made 8 or 10 years ago.

This is a most interesting subject for experiment, and this result is highly encouraging for further experiment and general use by the proprietor. But still there is almost every thing wanting to make this an *accurate* experiment of the effects, and the durability of green-sand *alone* as manure. The deficiencies are, 1st, the small space of the trial, 2d, the want of actual measurement of the quantity of the manure, (which was designed for and supposed to be at the rate of 30 bushels per acre; 3d, that it was on marled land, and no other; and 4th, and the most important objection, that the earth used contained a very considerable proportion of selenite, or gypsum, in very hard though moderately small crystals, which perhaps did not entirely dissolve, for years, and are not yet altogether used up by the crops, and so lost to the land. Thus it is impossible to judge whether the very obvious and profitable results are owing to the green-sand, or to the large quantity of gypsum (of the latter of which there must have been at least 4 bushels per acre) or to both, acting in connexion with the marl before applied. Capt. H. H. Cocke, (U. S. N.) the proprietor, stated that he made this rough experiment in the belief that the *gypsum* and not the *green-sand* was the valuable ingredient of the earth as manure. He also applied some of the same to land *not marled*, and found no benefit. He has since dressed some 30 or 40 acres with the same manure, and as he thinks with good effect; but as no precision was used in leaving a marked or regular boundary line, the effect could not be seen or appreciated at the season when we recently looked at the ground. We hope that Capt. Cocke will commence and carry through accurate and varied experiments, so as to show not only the value of this remarkable body of manure on his land, but also to show which is the fertilizing ingredient, and under what conditions it acts, or fails to act.

2. *Apricot tree in marl.*—At Evergreen, repeated attempts to raise apricot trees near the house had been unsuccessful. The trees died young, after bearing badly. The soil is a rich loam, on a clay subsoil. Some years ago, there was again a young stock of 5 or 6 trees, of suitable size to transplant. For experiment, one of them was transplanted to a walk, made of shell marl, (as a substitute for gravel,) and which was so compact and hard that it required good strength applied to the grubbing hoe to dig the hole in which to set the tree. The hole did not extend deeper than nor beyond the marl, and therefore the roots were placed exclusively in this hard bed of shelly matter. This tree has since been vigorous and grows well, and has begun to bear well. All the other trees, left in good and rich soil, declined, from the attacks of insects apparently, and not one of them is now alive.

The supposed cause of the benefit of the marl is that it cannot be penetrated and made a harboring place for the worm which bores into the tree near the crown of the roots, and the curculio which bores into and destroys the fruit while green. It has been already known in Delaware, (and was published in the Farmers' Register,) that laying about a bushel of marl to the roots and around peach trees, as they stand, (after laying bare the upper part of the upper roots,) was very beneficial to them. But planting them (and all other stone fruit trees) in a bed of marl must be a much better mode, if (as appears from the single fact above cited,) such a soil is not too calcareous for the health of the tree.

For the making of this experiment, as well as for the verbal report of it, we are indebted to Mrs. H. H. Cocke.

3. *Experiments with poudrette.*—Besides the report of Mr. Nicol (at page 97) of the ineffective application of *poudrette* last season, at Sandy Point, similar verbal reports have been made by Messrs. Robert G. Strachan and David Dunlop, of trials on their respective farms near Petersburg. The poudrette used by all was three barrels sent to us as a present, for the purpose of being tried, by the manufacturer, Mr. D. K. Minor, of New York. The supply was received too late for a full trial, as the corn had been generally planted. We made the best disposition of the manure, to three farmers who took pains to make as full trials as the advanced season permitted; and we regret to say that neither of them found any perceptible benefit. Still there can be no doubt of the great richness and value of the raw material from which poudrette is prepared, nor of the prepared article, if the mode of preparation be such as to secure from waste the fertilizing principles. If the fresh human excrements were mixed or covered, with marl, or any mild calcareous earth, we should warrant the preservation of the principles and the value of the manure.—Ed. F. R.

REMARKS ON THE MAKING, PRESERVING AND APPLYING OF MANURES.

To the Editor of the Farmers' Register.

Sandy Point, February 26, 1842.

In the January number of the Register is an "Essay on the making, the preserving, and the applying of manures," on which I would take the liberty of making a few remarks. Passing over the preliminary observations of the writer, I will begin with his stable management. I am not aware that any farmer or owner of a horse, who pays a due regard to his own interest, the health and comfort of his horse, or to the most economical mode of making manure from that source, is in any doubt as to "how long this [stable] litter ought to accumulate before it is removed," and that is that it should be removed every day. The writer of the essay is, however, "of the opinion that it ought to remain until by its great heat it endangers the health of the animal." If stable manure, by its accumulation, and consequent and unavoidable fermentation, should become at all offensive or deleterious to the health of the horses themselves, that deleterious tendency must be in operation from the moment such an accumulation commences; nor can any thing prove more injurious to the health, or more entirely destructive to the comfort of the horse, and certainly none more slovenly on the part of the farmer, than the too frequent habit of many in allowing manure to accumulate in the stable. The essayist's plan of keeping "the stables clean, not by throwing out the old mass, but by putting in frequent supplies of fresh litter," is something like concealing filth by a coat of paint, and has nothing that I know of to recommend it. By the essayist's own admission, the health of the horse is endangered by the practice, and I know from experience that it is not the most economical mode of making manure, and that in scarcely any other position will stable manure become sooner fire-fanged and injured. In Loudon's Encyclopædia of Agriculture is the following remark. "The dung should be removed [from the stable] if possible wholly without the stable as soon as dropped: for the exhalations from that are also ammoniacal, and consequently hurtful. To this cause alone, we may attribute many diseases, particularly the great tendency stable horses have to become affected in the eyes."

The essayist gives the preference to the feeding of cattle in pens, and subsequently states, "here also, great cleanliness ought to be observed, which can easily be secured by frequent supplies of fresh litter." In pen-feeding, with the most ample and frequent supplies of litter, I have never yet been able to secure that amount of cleanliness so desirable to the health and comfort of the animals so fed. Cattle on whom there is no demand made either on their labor or produce,

may thus be kept in tolerable plight; but milch cows and working oxen can never be subjected to this mode of feeding with benefit to themselves or profit to their owners; nor do I think that a larger or equal amount of manure can be made by pen feeding, than can be made by the same number of cattle stall-fed, daily cleaned, and fresh littered. I believe, by the experience of those who have tried both modes, the preference is given, in point of quality if not quantity of manure, to that from stall-fed cattle.

The essayist's mode of feeding hogs is not such as I think would suit the judicious hog breeder. Filthy as the general habits of the hog are supposed to be, it is an animal that is greatly benefited by cleanliness in keeping, and especially in feeding. As a manure raiser, the hog is certainly a valuable animal, and will amply repay his owner for plentiful supplies of litter, and for having his sty or pen frequently cleaned out. The supplying, however, of hog-pens with "scrapings of roads, ditches, &c., or of rich deposites of mud," is, I think, at best of doubtful economy; and in a majority of instances the labor of hauling and depositing such materials in the pens is unnecessary, if not injurious. If the deposites of mud, &c., are rich, why not haul them at once to the fields to be manured? The fermenting of either of them in the hog pens cannot be attended with any benefit, unless they contain a large proportion of inert vegetable matter, approaching to the nature of peat, which in this climate very rarely occurs. In the Farmers' Magazine, vol. xv., p. 351, are the following remarks: 'Making composts, then, of rich soil of this description, with dung or lime, mixed or separate, is evidently, to say the least of it, a waste of time and labor. The mixture of earths of this description with dung produces no alteration in the component parts of the earth, where there is no inert vegetable substances to be acted on; and the mixture of earth full of soluble matter with dung and quicklime, in a mass together, has the worst effects, the quicklime decomposing and uniting with the soluble matter of the earth as well as that of the dung; thus rendering both, in every case, less efficient as manures, than if applied separately from the quicklime, and even the quicklime itself inferior as a manure for certain soils, than if it had never been mixed with the dung and earth at all."

The essayist's theory, "that liquids are quite as necessary, and even more so, in exciting and hastening the decomposition of the litter than the solids are," appears to me unqualified. That moisture is necessary to induce fermentation cannot be doubted; but it is equally certain that an excess of moisture is destructive to and affords to the farmer the best means of checking and preventing injurious fermentation.

On the preserving of manures, the essayist observes, "As a general rule, manures ought always to be used, or at least placed in a situation to be used, as soon as thoroughly made;" and subsequently occur the terms, "properly made," "fairly made," "fully made." I would ask the writer, when is manure thoroughly, properly, fairly, fully made? On this point much diversity of opinion prevails. If I, from some experience, might venture to give an opinion, I would say that the slighter the degree of fermentation which takes place before manure is applied, as a general rule, the better. In colder climates, the bringing on of an incipient fermentation in manure before its application to the soil may be a desirable object; but in this climate the difficulty appears to me to be, with the judicious farmer, not in obtaining or facilitating but in preventing fermentation. On this subject, and for the climate of England, Davy speaks as follows:

"A slight incipient fermentation is undoubtedly of use in the dunghill; for by means of it a disposition is brought on in the woody fibre to decay and dissolve, when it is carried to the land, or ploughed into the soil; and woody fibre is always in great excess in the refuse of the farm.

"Too great degree of fermentation is, however, very prejudicial to the composite manure in the dunghill; it is better that there should be no fermentation at all before the manure is used, than that it should be carried too far. This must be obvious from what has been already stated in this lecture. The excess of fermentation tends to the destruction and dissipation of the most useful part of the manure; and the ultimate results of this process are like those of combustion.

"It is a common practice amongst farmers to suffer the farm-yard dung to ferment till the fibrous texture of the vegetable matter is entirely broken down, and till the manure becomes perfectly cold, and so soft as to be easily cut by the spade.

"Independent of the general theoretical views unfavorable to this practice founded upon the nature and composition of vegetable substances, there are many arguments and facts which show that it is prejudicial to the interests of the farmer.

"During the violent fermentation which is necessary for reducing farm-yard manure to the state in which it is called *short muck*, not only a large quantity of fluid, but likewise of gaseous matter, is lost; so much so, that the dung is reduced one-half, or two-thirds in weight; and the principal elastic matter disengaged is carbonic acid, with some ammonia; and both these, if retained by the moisture in the soil, as has been stated before, are capable of becoming a useful nourishment of plants."

The essayist's observation on the best mode of applying manures, "that he has come to the conclusion that the application of rotted manure as a top-dressing, and the coarse and unrotted to be immediately ploughed under," is contrary to the experience and practice of many intelligent and observant farmers. The shortest manures are doubtless the best adapted for winter and spring application, for any hoe crop immediately following. For example, the application of coarse litter, such as straw or corn-stalks only partially decomposed, to a field previous to planting corn, will cause serious impediment in the subsequent culture of the crop, and without any appreciable benefit to this or the following crop. On the other hand, the application of such manure, and also of dry straw, leaves, &c., which have undergone no previous fermentation, as a top-dressing on clover, is attended with the happiest effects, both to the clover and succeeding wheat or corn crop. I have seen finely rotted manure, dry straw from the stack, and dry and recent leaves from the woods, applied to clover side by side, and the best results were from the covering of dry straw. I have also seen young wheat top-dressed with pine

leaves (on marled land) with benefits which, though of course less in degree, were as distinctly marked as I have ever seen from the application of rotted stable or farm-pen manure. Numerous authorities might be quoted in support of using manure as a top-dressing, having undergone little or no fermentation, both from English and American writers. A frequent and valuable contributor to the Register, J. M. Garnett, esq., is one whose opinion must be familiar to every reader of your valuable periodical. A. NICOL.

AN ACT CONCERNING THE BOARD OF AGRICULTURE.

Passed February 3d, 1842.

Be it enacted by the General Assembly, That the members of the Board of Agriculture, authorized by an act entitled "An Act to establish a Board of Agriculture," passed March the twentieth, eighteen hundred and forty-one, be, and they are hereby, allowed the sum of three dollars per day each, for the time they have been, or may be, in actual session, and all reasonable expenses incurred by them, in travelling to, and returning from, their place of meeting.

All charges incurred by the corresponding secretary, postage paid by the members of the board, in discharging the duties imposed upon them, by the act aforesaid, together with the stationary used by the board, shall be allowed, and when admitted by the Governor, shall by him be caused to be paid by warrants on the Treasury.

This act shall be in force from the passing thereof.

[The foregoing act would have been published in the preceding number, but for the disappointment of two efforts, made by letter to different members of the legislature, to procure a copy.

Owing to the like want of authentic information, and relying upon the scant and incorrect notices in newspapers, we were somewhat misled, both as to the features and the progress of the bill, when our remarks thereupon were inserted in the January number. The errors, however, were unimportant, as the act now, such as it is, is completed, and speaks for itself.—ED. F. R.]

REMARKS ON SEEDS AND SEEDSMEN—SOWING SEEDS, CAUSES OF FAILURE, &c.

From the New Genesee Farmer.

The production of living plants from small grains of seed dropped in the earth is one of the most wonderful and beautiful operations of nature. When examined by the light of science, it is found to be effected by the combined agency of earth, air, moisture and heat; and to ensure success it is necessary that these four elements be combined in due but different proportions, according to the nature and habits of the different kinds of seeds. Hence arises the difficulty of causing some kinds to vegetate; and the uncertainty which gardeners generally feel respecting many of their crops until they see the young plants appear. Hence, also, arise most of the complaints which are made to seedsmen, and the censures which are unjustly cast upon them by inexperienced cultivators.

In order to explain this subject, and with a view to lessen the evil, the proprietor of the Rochester seed store has added the testimony of several highly respectable and successful cultivators in the country, and some accounts of their methods of preparing and sowing several of the most important kinds of seeds that are liable to fail with careless management.

The editor of the Albany Cultivator, speaking on this general subject, says:—

"Seeds often fail to grow; and the seedsman is often faulted, for vending bad seeds, when the cause of their not growing is owing to the gardener or planter. To induce germination, moisture, atmospheric air, and a certain temperature, are indispensable; and it is also requisite that light be excluded from the seed, until the nutriment of the seed is exhausted, or until the root can draw nourishment from the soil. The first effect of the air, heat and moisture upon the seed is to change its properties—to convert its starch into sugar—into a sort of milky pulp, the proper food of the embryo plant. If at this stage, the seed becomes dry, its vitality is believed to be destroyed; but if these agents are permitted to use their influence, the contents of the seed swell by degrees, and the first point of the future root having formed, breaks through the shell in a downward direction, and about the same time the first point of the future stem comes forth in an upward direction. Air, heat, and moisture are as indispensable to the growth of the plant, as they are to the germination of the seed.

"Now it often happens, that when seeds are planted in fresh stirred ground, or when the soil is moist, they undergo the incipient progress of fermentation, and the earth not being pressed upon them, and dry weather ensuing, the moisture is abstracted, and the seeds perish. Too much moisture is also often destructive to the vital principle of seeds—and others again are buried too deep to be vivified by solar and atmospheric influence.—The first object in planting, therefore, should be to place the seed just so far under the surface, and so to cover it with earth, as shall barely secure to it a constant supply of moisture. There are many seeds, as of the carrot, parsnip, orchard grass, &c., which if not previously steeped, or the soil well pulverized and pressed upon them, fail to grow for want of moisture. Hence, in sowing orchard grass, it is found prudent to spread it upon a floor and sprinkle it with water, before it is sown, and to pass a roller over the ground after the seed is sown; and hence, in light garden mould, it is advisable to press, with the hoe or spade, the earth upon all light seeds after they are sown."

On sowing flower seeds.

David Thomas, an experienced and very successful florist, remarks:—(N. G. Farmer, vol. 1, p. 56.)

"For large seeds, like the bean or the pea, a coarse soil is well adapted, as they can force their way to the surface from any moderate depth: but small seeds require different treatment; and we

lay it down as a safe rule, the finer the seed, the finer should be the soil.

"How does nature, exemplifying Supreme Wisdom, sow her most delicate seeds? She scatters them on the shady ground, trusting to the rain or the frost to cover them, (of course slightly,) and they germinate before the sun has acquired power enough to scorch them. The dust-like seeds of the orchis and cypripedium sometimes grow in beds of damp moss.

"Common garden loam, whether clayey or sandy, is much improved by a dressing of vegetable earth from the woods, well mixed before planting. If prepared in the preceding autumn, and pulverized by the frost, all the better.

"Such a soil is favorable to seeds of almost any kind, but *essential* to the finer and more delicate sorts. The preparation of the soil alone, however, is not enough. Fine seeds may be smothered if covered from more than one-eighth to half an inch deep; and their short roots may be parched if exposed to the sun except in the morning and evening. To a *fine soil*, therefore, we must add the protection of *shade*, and in time of drought, a regular supply of *moisture*. If the seeds are sown in an open border, a sprinkling of water in the evenings is best, but carefully abstain from applying so much as will bake the ground."

On preparing and sowing onion seed.

W. Risley—(N. G. Farmer, vol. 2, page 38,) says:

"First soak the seeds in water from six to twenty four hours—some seeds being slower to admit moisture than others, is the difference in the time required. After soaking, drain off the water, and mix the seeds with a sufficient quantity of earth to absorb the moisture remaining on the seeds; stir them often that they may vegetate evenly, and keep them in a moderate degree of warmth and moisture until they are sprouted, when they are ready to put into the ground. If the weather should be unfavorable, put the seeds in a cool place, which will check their growth. * *

"It was left in that situation until the time of sowing. In April, as soon as the soil was sufficiently dry, the ploughing was commenced, and the second day, at night, the sowing was finished, with seed prepared as before stated. *In one week the onions were up*, rows were soon visible near twenty rods, and no weeds yet appeared. The operation of stirring the soil with rakes and hoes was then commenced, and the weeds were not suffered to grow during the summer. (It is a mistaken notion that it is not time to hoe a garden until it is green with weeds.) The first of September the onions were harvested, and the product was over *two thousand bushels* of fine onions from two and a half acres."

On soaking mangel wurtzel seed.

J. Rapaljee says, (N. G. Farmer, vol. 1. p. 149,) "I prepared half an acre of land for mangel wurtzel, and obtained the seed from your agent at Canandaigua. After soaking the seed one day, I commenced sowing; but rain came on, and the soil being rather clayey, it was a whole week before I could sow the remainder. The seed was soaking all this time, and supposing it was spoiled or injured, I sowed it thicker than usual, and had not enough to finish the ground. Accordingly I sent to the same place and got more seed, and sowed the remainder without any soaking; so that part of my ground was sowed with seed soaked one day, another part one week, and a third part not all.

"Now for the result:—The part soaked one week, came up first, and much too thickly;—the part soaked one day, came up slowly and very thinly; while the part not soaked, did not come up at all. Thus showing conclusively, the necessity of thoroughly soaking these seeds, and the little danger there is to be apprehended from soaking too long. I am confident that inattention to this subject is the most frequent cause of the failure of the mangel wurtzel and sugar beet seeds."

William Garbutt, (N. G. Far. vol. 1. 20,) says, "much complaint is sometimes made of mangel wurtzel and sugar beet seed failing to grow. These seeds are not quite as sure of vegetation as some kinds; still, if rightly prepared, and sown when the ground is in good condition, before the weather becomes too dry, they will very seldom fail. The seed should be *soaked* in soft water, standing in a warm place, *for three or four days* before sowing. The shell of the seed is very hard, and requires a long time soaking for it to become softened so that the germ can burst it open. I have sometimes known it fail after being soaked, owing to late sowing and dry weather."

Planting too deeply. In vol. 1, p. 97, W. R. Smith states that he "planted half an acre of mangel wurtzel with two pounds of seed from the Rochester seed store. In a few days some scattering plants made their appearance. * * * Well, nearly two weeks after, I was surprised to find a fair number of plants just peeping through, and from their weak and thin appearance evidently wearied with their journey to the surface, which they never could have reached if the soil had not been light."

Parsnip, carrot, celery and parsley seeds are all slow to vegetate, and if sown late, and dry weather succeeds, they will not often come up. These seeds should be sown early, in fine soil, rolled or pressed down and kept moist. Mr. Geo. Sheffer of Wheatland, raises large quantities of carrots for feeding. He soaks the seed 48 hours, then rolls it in plaster, and when sown covers it from one half to three quarters of an inch deep.—(N. G. Far. vol. 2. p. 181.)

Cucumber, melon and squash seeds, seldom lose their vitality by age or otherwise, but when sown they often fail to grow, owing to the ground being cold or wet. These, and some other seeds, will invariably rot if sown too early—before the ground is sufficiently warm. *Lima bean and sweet corn* often fail from the same causes.

Egg plant seed will not vegetate in the open ground—it requires a good hot-bed.

Locust seed must be thoroughly scalded, by pouring boiling hot water and letting it soak 24 hours.

SUCCESSFUL CULTURE OF SILK IN 1841.

Extract from a letter from Robert Sinclair, sen., near Baltimore.

To the Editor of the Farmers' Register.

* * * I succeeded admirably in raising silk the last season. I sold for cash to the amount of

$357; and I am fixing to raise largely next season, having a good house well fixed, plenty of trees, and 80 ounces of good eggs, hands about me who have now had some experience, and from some account of cost kept last season, I am confident that, after having the three above requisites, I can raise silk in the cocoon state at $1 per bushel, or say what when reeled will make one pound. * * * * * *

ON THE CAUSES OF DETERIORATION OF THE WHEAT CROPS IN VIRGINIA.

For the Farmers' Register.

The causes which have led to the failure of the wheat crops in Virginia, for a succession of years, deserve the deep consideration of every farmer; and I am gratified to perceive that the subject is becoming one of public discussion. It is with the view of contributing my mite towards the elucidation of these causes that I submit the annexed observations; though I have had but little connexion with practical agriculture for several years.

For the last twenty-six years, during which I have been an observer of the progress and maturity of the wheat crop, a very great but gradual change has taken place in the time of ripening. In 1816 and '17 my harvest of the later varieties of wheat, growing on a heavy and rather slow soil, was commenced on the 17th and 18th of June. The earlier varieties, the old purple straw and May wheat, then extensively cultivated, but now extinct, usually came to the scythe from six to ten days sooner. Ten or fifteen years previous to that period, I have heard that the May wheat was frequently harvested in the month from which it derives its name. From 1816 downwards my memorandum book shows that the harvests became later and later; and last year, in the region of country in which I reside, there was scarcely a field of wheat ripe enough to be reaped before the 25th of June, and the harvest extended several days into the month of July. It was perhaps the latest harvest that we have ever known, though there have been several seasons in which a large portion of the wheat has not been in a condition to cut before nearly the close of June.

Another fact, which all farmers have doubtless observed, is that in proportion as the period of harvest is protracted, whether by the season or the variety of wheat cultivated, the more indifferent is the crop. A late crop is almost invariably attacked by the rust, which is decidedly the most formidable enemy we have to contend with. A long series of observations on the weather has convinced me that, from about the 20th of June to the 1st of July, we have a regular accession of hot, sultry weather, accompanied by frequent showers, most disastrous to the wheat that has to ripen during that interval. This state of the atmosphere recurs with as much uniformity as the "long spell in May;" and equally with the latter may be considered as in accordance with the laws which influence our climate. In the one, for the most part, the wheat is in flower; in the other it has to mature. When the harvests were earlier, as they were twenty years ago, the wheat was generally in blossom before the recurrence of the wet season in May, and there was consequently less of scab and blight, and open shuck, than of late years. The organs of fructification had performed their office before they were mutilated by the storms of the season. And in regard to the last half of the month of June, what farmer has not frequently beheld his fields of wheat wither and dry up rather than ripen, beneath the influence of the scorching rays of the sun? Even if it escapes the rust, which it seldom does under such circumstances, the weather is too hot for it to come regularly to maturity; and hence a light product, with very rare exceptions, must be the consequence of a late crop.

The obvious inference to be drawn from these facts is, that farmers should exercise the utmost precaution in the selection and preservation of their seed, and in the cultivation only of the earlier varieties. In the time of flowering they should aim to anticipate the long spell in May; and in the time of maturity, the sultry spell of June. This course, judiciously followed, will go far towards arresting the evil. But it will require care and perseverance. It was formerly practised with great success by the manager at Maiden's Adventure, in Powhatan, who selected every season from the earliest ears in his fields a bushel of wheat; and preserved his May wheat in the highest purity for a long time. His neighbors, for many miles around, were in the habit of sending to him for seed. The English farmers, by similar means, perpetuate the purity of their wheat, and keep each variety entirely distinct. Their example is worthy of all imitation; for as the failure of a crop of wheat in England is attended with far more disastrous consequences than it is in this country, it may be reasonably inferred that they have learned well how to multiply guards for its security.

The means here indicated are within the reach of all; but they do not constitute all that is necessary to the highest state of productiveness of the wheat crop. A great deal depends also upon the *soil;* so much so that the opinion is very generally entertained that wheat soon degenerates in our soil and climate. Hill Carter, in a late communication to the Farmers' Register, directly avows his belief in this doctrine; though William Carmichael appears rather indisposed to subscribe to it.

A highly cultivated plant is like a highly improved animal: neither will bear neglect without manifesting a tendency to deteriorate. Each is in some measure an artificial production. The race horse requires the greatest care, to be maintained in the full possession of his qualities; the short-horn cattle can only thrive on the most abundant and nutritious fare; and in like manner, the plant in its state of amelioration can only be kept up by a supply of that food which is indispensable to its full developement.

In respect to climate, the changes which the seasons have undergone in the last 25 or 50 years must be almost imperceptible. Natural laws are so uniform in their operation that we are hardly justified in supposing that there has been any departure from their ordinary course. If there has been any change, it has been one of amelioration, and therefore propitious to the earlier maturity of plants. But our soils by a long train of cultivation may have become partially or entirely ex-

hausted of that particular aliment which is essential to the production of wheat in its highest degree of purity. If they are thus exhausted, then we can no longer expect to derive perfect crops from imperfect seed. As a general rule, like will produce its like; a robust offspring is not the product of diseased parents. It is well known that it is only on lands containing lime, in some form, that the grain of wheat can attain its perfect developement. If the proper care had been exercised in the selection of seed, and the wheat grown on land adapted to its perfect production, it appears impossible that there could be any degeneracy, or that it should be later in reaching maturity now than formerly. But our soils, instead of being limed, have been enriched by putrescent matter; and in most instances the seed is probably saved from the most luxuriant growth, from rich lots or highly manured fields. The tendency to run to straw is thus encouraged and perpetuated instead of being corrected. Rust, and blight, and smut are the natural consequences of this state of plethora; the time of ripening becomes gradually protracted; and the farmer wonders why his wheat, that looked so promising in the spring, should be such a total failure at harvest.

In the first vol. of the Farmers' Register there is a translation of a highly interesting paper by Professor Bronn, of the University of Liege, "on the influence which the seed exerts on the quantity and quality of the crop produced from it, according to the different nature of the soil and climate from which this seed has been procured." From a number of well-established facts in vegetable physiology, he deduces the following law: "that every thing which favors the disproportioned growth of vegetables, opposes or retards their propagation or formation of fruit; and *vice versa*, the formation of fruit is hastened and forwarded at all times when exterior circumstances prevent the full developement and disproportioned growth of the stalk." The whole paper is of great interest to the agriculturist, and I would suggest its republication at a convenient time.*

This physiological principle furnishes us with the true theory respecting the important subject of a change of seed; and in the absence of a soil adapted to the wants of the wheat plant, as well as the means of rendering it so, our chief reliance will be found in obtaining seed from proper localities. There is scarcely a farmer who does not change his seed wheat, more or less, every year or two. Indeed, his discouragements have been so great, that he is continually on the watch for something new, in the hope that he will at last find a kind of wheat that will flourish on his land. Let him proceed upon correct principles, and there can be no doubt that he will derive material benefit. Supposing his lands to be destitute of calcareous matter, as all our soils are, he should obtain seed from a limestone country. His object is to reduce the quantity of straw, which is already too great on our improved lands, and increase the quantity of grain. A calcareous soil does not yield a great growth of stalk, and the qualities of the plant are transmitted to its offspring for two or three generations. That the qualities are thus transmitted is asserted by Professor Brown, and established by repeated experiments, both in the culture of wheat and other plants.

Some years ago I travelled, during harvest time, through the western part of New York, one of the finest wheat growing regions in the United States. Its soil contains so much calcareous matter that it is frequently found to effervesce when mixed with acids; and accustomed as I had been to witness the growth of wheat on lands made rich by putrescent manure, far more luxuriant than what I saw there, their crops did not present a very imposing aspect. Fields which I was told would yield from 25 to 30 bushels to the acre, would not have been adjudged in Virginia to produce more than 10 or 12 bushels. This is the kind of growth we should endeavor to secure; and next to having calcareous matter in our lands it is most desirable to have seed produced on calcareous soils. From New York then, or from Pennsylvania, or the valley of Virginia, or any other limestone region, we should renew our seed. And the facilities now offered, by the numerous seedsmen in our towns, are so great, as to place it within the power of most farmers to obtain from time to time a few bushels, which is all that is requisite for a supply.

Every farmer has witnessed the eagerness with which new varieties of wheat have been sought after; and he has also experienced the disappointment of finding them to become entirely worthless in the course of a few seasons. I could perhaps enumerate some ten or twelve varieties that have been cultivated within the last twenty-five years. Each was highly extolled, and all produced well for a time. We also know that on some farms, or in some neighborhoods or districts, a variety of wheat continues to be cultivated with success longer than in other neighborhoods. The only reason for this result that I can conceive is, that where a given variety flourishes longest, there the soil is best adapted to its healthy growth. The owners of such lands have it in their power, at a moderate cost, to render them in a great measure exempt from that sterility which, as it regards the production of wheat, has overtaken the most of our soils.

A striking case in point, in support of the view I have attempted to explain, in relation to a change of seed, is offered by the famous Italian spring wheat which attracted so much attention in Virginia a few years ago. For the first season the product was good; in some instances it was even extraordinary. Hence it was inferred that spring wheat might be cultivated permanently in our hot climate. The whole amount of success that attended its culture, as subsequent experience fully demonstrated, was to be ascribed to the quality of the seed, which being obtained from a soil admirably adapted to the perfection of the wheat grain, gave it an ephemeral vitality, during a favorable season, which enabled it to overcome the influence of opposing causes. After the first year, there were few cases in which more than the seed was reaped.

But the most interesting and conclusive facts in support of the value of a judicious change of seed were furnished by the late Benjamin Harrison, in 1838. [See Farmers' Register vol. vi. page 129.] He several times obtained a few

* This request shall be complied with in the next number.—Ed. F. R.

bushels of seed from Frederick county in this state, and the result was uniformly a great yield the first and second years, and a very good yield the third; after which his crops from the same seed rapidly deteriorated. Out of a number of experiments, the only failure he sustained was in the last trial he made; to wit, in 1841. He represented the wheat as ripening very late, and being attacked by the rust. But I have shown that late wheat has no chance to come to perfection, especially during such a season as the last;—the influence of climate being then fully sufficient to counteract the action of other causes, how favorable soever they may be.

I am aware that the editor of the Farmers' Register considered the results of the above mentioned experiments as in conflict with Dr. Bronn's principles. But the application I have attempted to make will, I hope, satisfy him that they are in perfect harmony with them. We assume that the seed was obtained from a soil well adapted to its developement, and transferred to another soil less favorably constituted. And so far as the influence of climate was concerned, the change was likewise to one of a less genial character. It follows then of necessity, that the result could not have been otherwise than comparatively favorable, provided there was no extraneous cause to produce disaster.

It has been thought by many persons that old wheat was better for seed than new. It is a well known fact that many species of plants grow with less vigor from old seeds. The chief value, if value there be, may therefore consist, in the case of wheat, in the diminished tendency to make straw, and in the greater tendency to produce grain. This point can be well observed and the comparative result reported by E. Ruffin, Jr., who has detailed a series of interesting experiments in the last number of the Register, some of which, and this amongst the rest, are yet in progress. It would also be gratifying to many readers to be informed whether the old wheat suffers as much from the depredations of the Hessian fly.

After all, however, the only effectual and permanent remedy for the disasters which have befallen the wheat crop, is to improve the land; to impart to it those constituents of a good soil in which it is obviously deficient. All other means are mere aids and expedients, valuable as far as they go, but of temporary duration. T. S. P.

ON THE CULTIVATION OF THE CORN CROP.

To the Editor of the Farmers' Register.

Chericoke, March 18th, 1842.

When we were last together, you expressed a wish, that I would furnish for publication in the Register, my method of cultivating the corn crop. This, as you wish it, I have no hesitancy in doing, and the more readily, as I consider all tide-water farmers labor under a debt of gratitude to you, for your "Essay on Calcareous Manures," and I may add, for the ardent, and zealous labors of a well spent life, so far as it has gone, in behalf of agriculture, which do all they can, they can never repay. In saying tide-water farmers, I do not at all mean that no other part of the state or country has been benefited by your labors, as I believe all have, or could have been, had they chosen to profit by the precepts you have so long and so ably inculcated, whether it is east, or west, north, or south; for the same great truths and principles that are applicable to our section of country, as to the improvement of soils, under the same circumstances must be applicable to another, and indeed to all; for the first thing, and the greatest desideratum with all intelligent and judicious farmers, I presume must be, if it is possible to make their lands rich, or if rich, to keep them so; for it is only by rich lands that a farmer can make or keep himself rich. The first thing then I should think a judicious man would do, in taking possession of an estate, if it was sterile, would be to inquire into and ascertain the cause of its sterility, and if possible to correct it; and if on the other hand he found his lands already fertile, that very rare occurrence in lower Virginia, it would be equally prudent in him to ascertain its true character, and the way in which this fertility could be maintained. And now (having had a pioneer to go before to point out all these things to us, to enable us to do, what without the aid of science never could have been done, viz.: to make a naturally poor soil rich, and to point out to us, too, that where we most needed the fructifying principle, we had it in most abundance,) I again ask the question, is not he that has done so much for us, deserving of all the praise, and all the gratitude we can give? I trust, sir, you will pardon me for this digression, but it is really what I feel, and what every tide-water man should feel, in lower Virginia or wherever marl or lime is attainable.

I will now, sir, resume the subject for which this communication was intended, to wit, my method of cultivating corn; although I do not know I that I shall advance any thing new, or that any body will fancy my way preferable to his own; as corn making is a subject upon which most farmers think their way is preferable to all others, and I dare say most of us are rather too well satisfied with our own notions, and way of doing things, else perhaps agriculture would go ahead faster than it does, and more science would be brought to its aid. And again the same system of tillage applicable to us, on our light lands, might not be so on different soils. But as I think the method that some of us pursue in this neighborhood a good one, wheresoever applicable, I will even say on. In the first place, then, I delay as long as possible in breaking up my corn land, so as not to finish until the planting season arrives. I am aware that in this practice I am singular, but nevertheless I think it a correct one. One very important reason with me is, that it saves from sprouting a vast quantity of clover seed, that would otherwise be lost; as every one, I presume, has noticed upon early fallowed clover land how thickly the seed came up in the spring, which all of course must be killed in the cultivation of the corn crop. Another reason is that it saves at least one month's work in the after-culture of the crop, as the weeds and grass seed do not find their way up at all, generally speaking; as from the time the ground is ploughed to the laying by of the crop, the drags, cultivators, and ploughs are always going. And thirdly, but not lastly, as I could give other reasons, I think land injured by an exposure to the

winter's frosts and wind. The covering with which nature has clothed it, as a protection from the winter blasts, keeps it, I think, in a better state for the summer's crop, than when it is exposed by a fall fallowing. If the land is stiff, and is ploughed in the fall, it requires another in the spring, and is then almost sure to be ploughed too wet; and I really think it a fallacy, in supposing that decomposition of the vegetable matter turned under in the fall can take place in the spring, before the return of warm weather.

When, however, my ploughing is done, it is done in the best way, with large ploughs, as I do not design any thing that is turned under shall again see light, until the three-horse ploughs are again brought into operation for a fallow for wheat. The depth of my ploughing is regulated by the depth of soil, as I never designedly turn up a *caput mortuum*.

If the land is any other than very light and dry, we bed in fifteen feet beds, so as to leave three corn rows on a bed. As soon then as the ploughing is finished, we put on the drags, and dress the surface as nicely as possible. The ground is then laid off in five feet rows, with a trowel hoe plough, and the corn planted as soon after as possible; beginning as soon in April as we can. We plant by a string going across the rows, or beds as may be. In common land we plant at the distance of three feet the narrow way, in pretty good land two feet, and in good land three feet with two stalks to each hill. I think it decidedly better to double or triple the stalks in the hill, than crowd it too much the narrow way, as I think corn, as well as all other grain-growing plants, requires air, as much as sun, or rain. As soon as the planting operation is finished, the drags go to work again, so as to get over the crop by the time it begins to come up. As soon as it is up, we put in the single horse cultivators, (five teeth, square cutting edge, and working square to the front, about two or two and a half inches wide, fixed *echelon* fashion in one beam, the horse pulling by the other,) generally I believe called the X cultivator, (the only kind of all the varieties of that plough I have ever seen worth a cent.) Then we run as close to the corn as possible, going three times in a row, generally getting over twice before the corn is high enough to take earth, say knee high, or more. As soon as it is, we put in the single-horse plough, lapping the earth on the corn; we now put on the hoe hands, (having previously thinned as soon as it was large enough to bear the operation,) and that the ploughs may be enabled to keep way for the hoe hands, we now go on with four furrows. The weeding, by the way, is only a nominal thing to level the land, to straighten any stalk of corn the ploughs or other causes may have bent. As soon as we finish with four furrows, we then go back and split open the middles. This brings us to about the beginning of harvest, when the cultivators are again put in, and run to level down the beds, and to keep down the young grass, and to keep the land always open for the reception of light, air, and moisture, the great nourishers of vegetation. We go over the crop with the cultivators after using the plough once or twice before we finish, according to the forwardness of the crop. We cease then until the corn is in full shoot and tassel.

The practice of backing off the land from the young corn, as soon as it comes up, with large or small ploughs, I think cannot be too much deprecated. It is, I know, the prevailing method of cultivating corn in this section of the state; and I know, also, that very many good crops have been made in that way. Corn is a very vigorous plant, and with good cultivation, in good land, work it as you may, will bring a good crop. But still, I think the practice of backing off the land from the young corn a very bad one, as it evidently gives us double the hoe work, exposes the grass seed and roots to the light and air, which vegetates them, and starts them all to growing, and moreover brings up the vegetable matter just turned in, it don't matter whether of fall or spring, then to be exposed to the air to dry, and interfere with the after cultivation the balance of the year, instead of remaining under the earth, to decompose, preserve moisture, and afford food for the growing plant. The great secret, if any there is, in cultivating the corn crop, is always to keep the surface stirred and clean, never suffering a crust to form on the land, that thereby the roots of the plant may have free access to light, and air, and all the moisture it can get, whether from rain or dews, and no weeds or grass to take from the growing crop. To those who use cultivators, in the tillage of the corn crop, I would advise them always to keep ahead of the grass, as, if the grass gets ahead of them, the cultivators will not subdue it.

I have followed the above method of cultivating the corn crop for some years, and have succeeded very well with it, and have never had a grassy field since I commenced it. It saves time, much hoe work, and I think makes the crop more sure. Indeed I do not think it takes more than half the labor of the ordinary method; and to those who sow small grain in the fall after corn it gives a clean cornfield. If, peradventure, this communication should fall under the eye of any other than one of the family of the "good-enoughs" I would advise him to try it, provided always his land, &c., suit.

CORBIN BRAXTON.

PAINTING HOUSES.

From the Farmers' Cabinet.

It has long been a subject of inquiry as to the best time to apply paint to the clapboards of houses for durability. Repeated experiments have been made, within twenty-five years past, which have resulted in the conviction, that paint applied between November and March will stand more than twice as long as that which is spread in the warmest weather. The reason is obvious; for in cold weather the oil and the component parts of the paint form a hard substance on the surface of the clapboard, nearly as hard as glass, and not easily erased or even cut with a sharp knife, and will not soon wear off; whereas paints applied in the months of July and August, and more especially if in a severe drought, the oil immediately penetrates into the wood like water into a sponge, which leaves the lead *nearly dry*, which will soon crumble off.

REMOVAL OF THE OBSTRUCTIONS IN RED RIVER.

To the Editor of the Farmers' Register.

I have this day received from Gen. Williamson, the contractor under the United States for opening the raft on Red river, a letter dated the 19th inst., saying that the obstructions were removed, and that the steamer South Western had on that day passed through on her way to Fulton, a flourishing town some two hundred miles above the raft, and that the Harrisburg steamer, with a barge in tow, was in sight, and would be very soon also through.

It is part of the contract under which the river has been opened, that it shall be kept open for five years, after which time the stream will be so wide as to enable it to pass its floating drift wood, and take the same care of itself as other rivers. At present the river is so lessened in width by accumulations of alluvial soil on the sides, from the lodgment of its drift timber, that it will take the current some time to wash out a space equal to the size of the river either above or below these obstructions; and it is during this time, and for this object, that the contract is continued for some years, so as to assist the current, where it may from time to time show that it is needed, in widening its bed. When this is effected, it is but reasonable to expect that the river will keep itself open within the raft region, as it has always done for 500 miles above it, and as it now does below it. The town of Shreeveport was built some years ago above one hundred miles within the removed raft, and the river has kept itself clear to that place. It is now removed for fifty miles above that place into the unobstructed river, and where it is 200 yards wide, and that for several hundred miles above.

The opening of this great river, which may now be deemed certain, will give an inlet for brisk trade to steam boats, in a passage of five days from New Orleans, into unquestionably one of the finest cotton countries of the United States, whether we regard climate or fertility of soil.

The lands immediately on the river are naturally dry, light, and easy of cultivation, and yield on an average of years from 1500 to 2000 pounds of seed cotton to the acre, and under favorable circumstances on particular acres has yielded more than 3000 pounds, and in corn as high as 75 bushels. In corn it yields from 40 to 60 bushels to the acre. These lands are all owned by purchase from the government, or claimed by settlers with a view to a purchase when they shall be brought into market.

There are large bodies of good oak and hickory upland, running parallel with the river and convenient to it, that can be had at government price, and are now in the market for entry. The produce is various, from 600 to 1200 pounds of seed cotton to the acre, but from 600 to 800 pounds cotton, or 20 bushels of corn, may be about a general average. These lands are easy to clear, and free, light and easy to cultivate, and the country generally well watered and pretty healthy.

This country is worthy a visit from the planter, (which can be comfortably and cheaply made,) as it is perhaps the only part of the United States, taking into consideration price and fertility, that will enable him to make reasonable profits on the present price of cotton, which, it is to be feared, is neither accidental nor temporary.

VOL. X. APRIL 30, 1842. No. 4.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

ASHES AS MANURE.

From the New England Farmer.

The following is from "the Transactions of the Society for Promoting Agriculture in the State of Connecticut" :—

"What experiments have been made with ashes? On what soils, for what crops, and for what grasses? What success has attended the use? Are leached or unleached ashes most beneficial as a manure? Do they equally suit upon the same soils, and for the same crops? In what quantities are they to be used?"

Mr. Atwater, of Wallingford. I have made use of leached ashes, as manure for crops and grasses, and find it excellent for both upon dry land. When my grass fails, I plough up my land, and the ashes serve again as manure for a crop, and afterwards for grass. But ashes have not benefited my wet land, that was unfit to plough; for though they in most instances introduce clover, yet the land will soon be covered with moss, when it is rendered unfit for any thing, and if it cannot be recovered from the moss by ploughing, it is injured instead of being benefited.

Mr. Tomlinson, of Milford. We have found leached ashes to be excellent manure for flax.

Mr. Parsons, of Durham. I have used unleached ashes for many years, as manure for Indian corn. I put a handful round each hill, soon after the first hoeing, and have much benefited my crop by this method, having frequently omitted some hills, for the purpose of ascertaining the benefit derived from the ashes. I have always found myself richly repaid both for the manure and for my labor. The greatest advantage has accrued when a rain has followed shortly after my applying the ashes.

Mr. Noah Fowler, of Guilford. I have found, from experience, that leached ashes is a very beneficial manure for wheat and rye. It appears to me to be a great preventive of blasts.

Mr. Andrew Hull, Jr., of Cheshire. I have received great benefit from leached ashes as manure for wheat and rye. But I have not found that it prevented blasts.

Mr. Holcomb, of Simsbury. I have made use of unleached ashes, as manure, for Indian corn, and have derived great benefit from it on dry land. Whenever I have used it for corn, where the land was wet and heavy, it has been of no advantage to the crop at all.

Mr. Wadsworth, of Durham. One of my neighbors planted a field with Indian corn, and applied unleached ashes to thirty-six hills. During the first part of the season, the corn on which the ashes was put appeared much better than that in the other part of the field, to which no ashes was applied. When the corn was gathered, the thirty-six hills, to which ashes was applied and thirty-six adjoining hills which had none were measured, and those which had no ashes were found to be the most productive and to have the superiority over those on which ashes was put. This was on heavy land. The same neighbor made the experiment on light dry land. A part of his crop of corn was ashed and a part was not. Here the ashed corn much exceeded the other.

Mr. Eli Bronson, of Waterbury. In June, 1792, I ploughed a grass field, of a light sandy soil, where much old wood was burned. The ground was very dry. After harvest, I ploughed this fallow again. The drought continued more severe than was perhaps ever known in the memory of man. I observed that all the spots where logs were burned were much more moist than any where else. This circumstance particularly attracted my attention, as I had been taught that ashes were of a hot, droughty nature, suited only to wet land.

In 1795, I planted a wheat stubble, which was new land and sandy soil, which had been thoroughly burned when tilled for wheat. Part of the corn was dressed with a handful of ashes to a hill, at the first hoeing; here, for the first time, within my knowledge, ashes failed of producing any beneficial effect.

Soon afterwards I planted a tough sward, part of which was ashed in quantity as above. The part dressed with ashes grew remarkably, while the other appeared languid and pale, as if grub-eaten, until the second hoeing, after which it began to recover and to thrive better; but it finally produced not more than half as much as the part to which ashes was applied.

From the experiments of myself and my neighbors, I formed the conclusion that not only on new land, which has been recently burned, but also on land which has been kept mellow by tillage for one or two past seasons, and where little or no undissolved vegetable substance remains, no visible benefit accrues; of which the following facts may be considered as farther illustration.

In 1796, I planted corn after rye, the land cloddy and full of stubble; one end of it was very tough, and was planted with potatoes; a few hills of the potatoes, and most of the corn were ashed; some of the corn was dressed with gypsum—all was benefited, but the potatoes much the most.

In 1797, I again planted corn on cloddy land, encumbered with stubble. I carted on barn-yard manure, not well rotted. I ashed a part, by which the crop was enhanced at least one third.

In 1798, I fallowed a lot, much exhausted by ploughing. It was a dry loam, with tender sward. Carted on barn yard manure, ten loads to the acre, and ploughed it four times. I sowed half an acre with wheat, and strewed over the half acre a small load of leached ashes, and eight or ten bushels of unleached ashes. The wheat at first grew surprisingly, and though it did not hold out according to its first appearance, it yielded eleven bushels.

In 1799, I planted corn on buckwheat stubble, loamy soil—I ashed a part of it when coming up, and omitted one row. At first there was an apparent advantage, but by hilling time it could scarcely be discerned, except at one end, where it was somewhat cloddy, and there it might be perceived at harvest time. The other part I dressed with

gypsum, leaving one row as before: the success was the same as with the ashes.

The same year I planted a piece of sward land, loamy soil, and dressed the corn with ashes, omitting one row, as in the other field; began to hoe the corn seven days after the ashes was applied, when the hill in the unashed row, which we crossed in hoeing, was every where noticed from being yellow, while the other was a lively green. After the second hoeing, a second dressing of ashes was applied on part of the lot, but without effect, even on part of that row, which was omitted in the first dressing. About hilling time, the unashed row began to recover; but finally yielded at harvest, little if any more than half as much as the adjoining rows.

The same year, I observed the like good effect on corn, both from ashes and from gypsum, on tough sward, and on cloddy land, as applied by my neighbors, in sundry instances.

I have often found ashes, both leached and unleached, to be very beneficial to grass on dry land, but not on wet. I have never found them useful on my garden.

From my experience and observation, I conclude that ashes is best applied on dry grass land, or on land newly ploughed up, or where shades have lately been taken off, or where grass turf or other vegetable substances remain undissolved: in each of which cases, there is contained in the soil food for plants, unprepared for vegetation. To effect, therefore, a speedy preparation, ashes is an important application.

Whether ashes do, in fact, prevent worms, or destroy them when corn is eaten by them, I have not been able to ascertain; though they have been often supposed so to do, when no evil of the kind has existed. I have often, when corn has appeared languid and yellow, as if eaten by worms, taken up whole hills and carefully examined both the roots and the earth, without discovering any signs of worms. In these cases, I have deemed the unpreparedness of the soil to be the only evil. Ashes is then a sure remedy. But if the land be well tilled, the weather be warm, and there be frequent showers, it will be well prepared, without ashes, by hilling time or sooner; but the corn will not recover the injury it has sustained for want of earlier preparation. Hence it follows, that ashes on ploughed land should be applied as soon as vegetation begins.

It is best to apply leached ashes as soon as corn is planted, while a team and cart may pass without injury to the hills. But whether unleached ashes can safely be applied before the corn is sprouted, is a question I am unable to solve.

The usual quantity of unleached ashes for a hill of corn is about a gill: but it is worthy of being observed, that where a greater or even a less quantity has been applied, the effect has been much the same. The effects of ashes and gypsum, so far as the application of the two has fallen within my notice, appear to be much the same.

TO MAKE HENS LAY PERPETUALLY.

From the Cultivator.

I never allow cocks to run with my hens, except when I want to raise chickens. Hens will lay eggs *perpetually*, if treated in the following manner. Keep no roosters [cocks]; give the hens *fresh meat*, chopped fine like sausage-meat, once a day, a very small portion, say half an ounce a day to each hen, during winter, or from the time insects disappear in the fall, till they appear again in the spring. Never allow any eggs to remain in the nest, for what is called *nest eggs*. When the roosters do not run with the hens, and no nest eggs are left in the nest, the hens will not cease laying after the production of twelve or fifteen eggs, as they always do when roosters and nest eggs are allowed; but continue laying perpetually. My hens always lay all winter, and each from seventy-five to one hundred eggs in succession. There being nothing to excite the animal passions, they never attempt to set. If the above plan were generally followed, eggs would be just as plenty in winter as in summer. The only reason why hens do not lay in winter as freely as in summer, is the want of *animal food*, which they get in summer in abundance in the form of *insects*. The reason they stop laying and go to setting, after laying a brood of eggs, is the continual excitement of the animal passions by the males. I have for several winters reduced my theory to practice, and proved its entire correctness. It must be observed, that the presence of the male is *not* necessary for the production of eggs, as they are formed whether the male be present or not. Of course such eggs will not produce chickens. When chickens are wanted, roosters must of course run with the hens. B.

From the Maine Cultivator.

GRAIN—PRACTICAL HINTS, &c.

Norridgewock, March 5, 1842.

Messrs. Editors—I am apprehensive that my communications will become tedious to many of your readers, on account of the minuteness of my details; but if those to whom they prove so, will reflect a moment, they will be convinced that writers on agriculture are apt to go into the opposite extreme, and only write on general principles or striking facts; taking it for granted that every one is already sufficiently acquainted with the minute details, which is far from being true. Few of your readers but can recollect some simple labor-saving observation, in your useful paper, which has been of more value to them than one year's subscription. With these convictions I shall continue to speak of things no otherwise important, than having convenience and saving of labor to recommend them.

I object to mixing grass seed with grain, to save labor in sowing, as much of it would be covered too deep by the harrow and treading of horses or oxen. After sowing my wheat or other grains they are harrowed twice—grass seed sowed, and then rolled smooth. On sandy loam, half a peck of clover and the same of timothy or herdsgrass, is a good quantity. In clayey loams two quarts of clover and eight of herdsgrass is about right—varying the proportions according to the soils—in very wet and bog-land soils, the clover should be omitted and a half bushel of red top and a peck of herdsgrass sowed to the acre. As a general

thing we sow too little grass seed. The consequence is, a poor tilth is left naked, and the growth on a rich one is so rank as to lose much of its value. Some use a brush harrow to smooth their ground and cover grass seed. This may do on ground too wet to admit the roller, but is liable to drag the seed and leave it uneven. I would always sow chaff in preference to clear seed; but it requires observation and judgment; for a bushel of chaff, which will contain two pounds of seed one year, may not afford half that quantity another.

Every farmer ought to grow his own seed; it is always a cash article, and if he buys he has to pay for cleansing, which is useless, unless it contains foul seed. If leached ashes are used on wheat, they should be spread before cultivating: If unleached, they may be sowed any time before the plants are four inches high. Were it not for pressing the earth around the seed, I should prefer not to roll my grain of any kind, till it was three or four inches high. It will then destroy myriads of insects, and cause the grain to branch more.

If this mode will not break the eggs of the Hessian fly, I know no means of doing it. All that has been said or written on sowing quick lime, ashes, or impregnating fields with the fumes of tobacco, sulphur, or *essences of pole-cat*, to destroy the fly, in July or any other month, has never destroyed enough of them to pay a man for a week's work. Some wise man in our state, has advised to *starve them out* of the country by ceasing to sow. I should not like to see it tried, as I fear the experimenters would starve first. Although women and children are not employed here as in Europe, to weed and glean grain fields, and field labor is expensive, still I am satisfied from personal observation, that many fields of wheat will well reward an outlay of one to three, or even four days expended in weeding an acre. By thorough weeding once, the Canada thistle may be prevented from going to seed before harvest. Every farmer should have a pair or more of weeding tongs. They may be made of wood, exactly in the shape of a pair of blacksmith's tongs,—the handle about four feet long, and spread so as to permit the operator to stand between them. Mine have the jaws and joint made of iron, with teeth on the inside, a turned hoe-handle screwed on each shank, like a goose neck hoe. I have also a sharp gouge, one and one fourth inch wide, handle four feet long: with these an immense number of weeds can be destroyed in a day.

The advantages of early cutting are so numerous that I must dwell a little on them. As soon as the upper part of the stock is turned yellow and the kernel is fairly in the *paste state*, put in the cradle the first fair day—I say the *cradle*, for before the grain is crippled by long standing, this useful instrument *can* be used. If you neglect to cut then, you may have rains, and winds to ripen, break down and shell out the grain—if rusty, the quality grows poorer—you must cut with a sickle—the straw is too brittle for bands—you can only handle it when the dew is on, &c.

Unless you feel able to purchase the little machine, with fingers pushed before a pair of little wheels, for taking up cradled grain, which is a great saver of time and back-ache, you may follow the cradle with a rake made as follows: head 2 ft. long, 1½ inch square, 6 teeth half inch in diameter, 10 inches clear of head--handle seven feet long—a dry fir is the right shape and light—on the back of head and handle, instead of bows, nail a triangular piece of half inch board, with which to even the butts of the grain. If your grain is good, you may stand in your place and gather a sheaf. Those who understand it, can make five bands sooner than I could describe the process. By the way, I know men who can make a band and bind a sheaf quicker than others can do the former. There is a *cleverness* in handling grain, which few men have arrived at in this section. I have had men in my employ who could not average half an acre in a day.

It is safest to stook the same day you cut. I prefer twenty bundles to a stook, on account of the power to stand against the wind. It is made as follows: Set up four pairs and one at each end: one pair and one, on each side of the centre;—place four cap-sheaves on each of these points, and fasten together in the usual way.

Cradled grain is much less liable to hurt in the stook or barn, than that which is reaped, on account of its looseness. Much grain is injured by mowing down too soon. In fact it would be better never to put it in close mows. I saw a grain barn at Guilford, owned by Hon. Joseph Kelsey, in which he had one scaffolding above another, so that the wheat all stood on the butts. It could not hurt in this way. I cannot doubt the flour would be much sweeter preserved in this way.

As to the mode of thrashing grain, it has come to be more expensive than before any horse power machine was in operation. It is my deliberate opinion that the man who has grain enough to make it an object to feed cattle on it, will save time and money by using the flail in preference to any machine; unless he can have one in his barn to use as he pleases. Few farmers will afford this. The time lost in tumbling straw out doors and pitching it back again, with the hazard of injury from stones are serious evils, all of which are avoided by thrashing and feeding from the floor.

Of barley and oats next time. Yours, &c.

JAMES BATES.

PROTECTION OF CORN AGAINST CROWS.

From the American Farmer.

Mr. O. M. Whipple, of Lowell, Mass., says, in his statement to the Agricultural Commissioner of Massachusetts, that for 15 years he has preserved his corn from the depredations of crows, by sowing on his field a quart of corn soaked in a strong solution of saltpetre. We can believe this, as no crow which might have eaten half a dozen grains of corn well saturated with saltpetre, would live long enough to bequeath his estate to his interesting progeny, though a scrivener were at hand, at the time of his making his meal, to draw his will. Saltpetre judiciously used, possesses medicinal virtues, but when taken in excess, is destructive of life, and hence the protection it affords to seed corn soaked in a solution of it, against worms as well as crows.

The best *scare-crows* we have ever used were bright sheets of *tin* suspended from poles, by wires; the poles of sufficient height, and in sufficient numbers, to be seen all over the field. Four

or six, if judiciously placed, will effectually answer for a field of 50 acres. Our mode of fixing them was this; we cut a pole of sufficient height, trimmed off all the limbs but the upper one; to the end of this limb, we attached, by a strong flexible wire, a sheet of tin, and planted the pole thus provided firmly in the ground on the distined spot. The limb left at the top, should project horizontally far enough to allow full play to the tin. Thus attached, the slightest breeze gives motion to the tin, and consequently causes a reflection, so sudden as to effectually frighten off crows, or other birds addicted to picking up the corn. Three years successful use of such *scare-crows*, justify us in recommending them to our brethren.

From the Kentucky Farmer.

FORCING FRUIT TREES TO BEAR.

Greenup Co., Ky., March 3, 1842.

Dear sir—Having addressed you an epistle a fortnight ago, I did not at that time intend to write you again until I saw your comments upon the project proposed in that letter, but being under the conviction that I could not write too much for the good honest-hearted yeomanry of the land, provided I keep in the limits of valuable information, I have, by the idea of facilitating the labor of the producing man in some measure, been prompted to address you at this time, the main object of which is to apprise the agricultural community of a novel mode of raising apples. I do not wish to be understood that it is novel with all, for it has been practised in Europe for many years, by the farmers in Germany in particular, who probably are the inventors; but I mean that it is novel to me, and if not to all, in my knowledge is at least not practised by them. The steps to be taken by the farmer to force his fruit tree to bear, as it is termed, are of a very simple nature and can necessarily be executed by any person who turns his hand to it without the aid of a practical operator, further than a description of the process. I hope, therefore, that my agricultural friends will not deem the description which I am about to give of the process to force trees to bear unnecessarily minute. With a sharp knife (the blade of a penknife is the best) make a cut in the bark of the branch which is meant to be forced to bear, and not more than eight or nine inches from the place where it is connected with the stem, or if it is a small branch or shoot, near where it is joined to the large bough, (three inches or less,) the cut is to go round the branch, or to encircle it, and penetrate to the wood. Care must be taken not to cut the wood, which would necessarily cause detriment to the branch or shoot operated upon. A quarter of an inch or nearly from the first cut make a second in the same way round the branch or shoot, so that both encircling the branch or shoot, a ring is formed thereon a quarter of an inch broad between the two cuts. The bark between these two cuts is now taken clean away with the small blade of a penknife, down to the wood, removing even the fine inner bark, which immediately lies upon the wood, so that no connexion whatever remains between the two parts of the bark, but the bare and naked wood appears white and smooth; but this bark ring, to compel the tree to bear, must be made at the time when the buds are strongly swelling, just before breaking out into blossom. In the same year of this operation a callus is formed at the edges of the ring on both sides, and the connexion of the bark that had been interrupted is restored again without any detriment to the tree or branch operated upon, in which the artificial wound soon again grows over. By this simple (though artificial) means of forcing every fruit tree with a certainty to bear, the most important advantage will be obtained by those who watch the time nature is ripe for it. Three years ago (the time when I was first informed of this singular way of forcing trees to bear,) I made an experiment on an apple tree. Being somewhat cautious of humbuggery I confined the experiment to one branch of the tree, which was about a fourth part of the whole top of it. I did not notice it until May. I had partially forgotten it, as I had but little faith in its having any effect toward making the tree bear, and called by rather to see if the limb which I had cut was not dead than to observe any thing else; but to my astonishment I found the limb which I had expected to find dead in a vigorous state of life, with as much young fruit on it, apparently, as all the rest of the tree. On examining the young fruit, I found that on the branch which I had cut to be sound and firm, while that on the other parts of the tree were dwindled and very much decreased. I expected at first that it was owing to the cut which I had made on the branch, but I satisfied myself by examining other trees which I found to be in the same way, and which I found shortly afterwards to be falling off. In September, when I gathered the apples, I found that the branch of the tree which I had made the experiment on, had five bushels on it, and the rest of the tree had not above one bushel on it, and that was inferior fruit. I would therefore recommend that farmers who have orchards would try the experiment. It would be well for them to be particular in the operation at first for fear of damaging the tree.

WILLIAM R. THOMPSON.

AN ESSAY ON THE BEST SYSTEM OF ROTATION OF CROPS, (HOGS,) PORK BEING THE CHIEF SURPLUS OF THE FARM.

From the Kentucky Farmer.

The first rotation on a pork farm is corn, rye fed down to hogs, clover (seed sown on rye) two years. This rotation will improve the ground very fast.

In consequence of the probable injury that would be likely to be done to the corn crop by the worms, when following clover, that crop should be broken up in the fall or winter season, the sod being turned over in the fall of the second year the frost of winter will effectually destroy the cut worms.

The advantages of this rotation will be to furnish a succession of food suitable for the hogs, at the same time enriching the soil.

Without a proper supply of corn the raising of pork would be a poor business in Kentucky; and a proper supply of corn cannot be easily raised

except upon fertile land; and the fertility of the land cannot be kept up without making a proper return to the soil for the corn taken off. All this will be done by this rotation.

The corn in this rotation is the only exhausting crop. This exhaustion is more than supplied by the fertilizing properties of the rye and the clover. All that is produced of both rye and clover is returned to the ground, except so much as is retained by the hogs to make flesh and fat, and this waste is more than replaced by supplies drawn from the atmosphere.

The corn supplies food to finish fattening, and a part of this may be fed in the field where it grew, thus adding to the fertility of the soil. Where the corn is thus fed, rye may be sown in the field a few days before the hogs are taken out; and they in gathering corn will put the rye well into the ground. But I prefer ploughing it in, after the hogs are taken out of the field.

If the ground should break up cloddy the roller and the harrow should be both used; but if there should not be many clods the harrow alone will be sufficient to level the field. The importance of a level surface will be seen when the ground is in clover, and when it comes to be ploughed the next time.

The rye will afford the hogs early spring grazing and push them forward very fast with the addition of a little corn. This early spring grazing is very beneficial to hogs, besides being a great saving of more costly food. The rye will keep them until one of the clover fields is ready to receive them, which may be about the 20th of April. After they are put into the clover, if the weather should be cold, so that there will probably be frost, it would be well to take the hogs out of the clover field, and keep them out, until the frost is off the next morning. Frost does not hurt clover that is not disturbed at this time of year; but every branch and leaf that is touched whilst the frost is on it, dies down to the place where it was injured. In this way I once had ten acres of clover nearly destroyed one morning, by one hundred hogs passing through and feeding on it, whilst frozen. My other clover lots were not at all injured by the frost as they had no stock upon them that morning.

The clover will afford the hogs good grazing until the rye is ready for them, which will be about the first of July. When the hogs are first put into the rye, some should be cut and got out and put in the paths which are made by the hogs, that the young ones may learn to eat it, which they do not always learn readily, unless they are put in the way of knowing what it is.

Now when the hogs are taken off; one of the clover fields may be saved for seed. The rye will last the hogs, (if there is enough of it,) until corn is sufficiently advanced to commence feeding them with the new crop. And this is one of the excellencies of rye, that it will keep in the field longer than any of your small grains. If there should not be enough rye, the hogs will go into the clover fields again, and now, they would pay well for having a little corn thrown to them every day.

The clover seed should be sown upon the rye about the 10th of April. A bushel should be put upon ten acres and as evenly distributed as possible. A box ten or twelve feet long, made of very light materials and having divisions every foot, with holes in each division, sows clover seed more evenly than it can well be done by hand. After the field has been once set in clover, the seed should be allowed to ripen the fall it is intended to plough it up; which will furnish a sufficiency of seed to keep up the rotation without sowing again. If seed in the chaff is used there should be a bushel per acre.

In this rotation two bushels of rye should be put to the acre. This quantity will supply more grazing than would be had from less seed, and will also afford a better crop, by supplying enough to make up for the roots that may be killed by the hogs rooting them out of the ground. Hogs root in grazing rye much less than would be expected.

Then the rotation upon the hog farm will be corn, rye, each one year; clover two years.

But even on this farm I shall recommend another rotation. The family will want flour, and wheat cannot be raised in a rotation with rye without considerable mixture with the rye. Then here the rotation should be wheat, corn, wheat, clover ploughed in the second year for wheat again. Upon these fields the manure from the stables may be hauled the year it is in corn, and the ashes and chip manure the year it is in clover. The spent ashes is a most excellent top dressing to clover. Or the spent ashes may be used as a top-dressing for the wheat crop, or applied to the growing corn crop.

When the fertility of the soil is sufficiently advanced; two crops of corn, two crops of rye and two years in clover, may be the rotation. And in very rich land the rotation for several years together may be corn and rye alone.

From many years trial of this rotation of corn and rye, I cannot perceive that the soil has been at all injured in its productiveness. I have raised a crop of corn which was cut up in the usual way, and the field sowed in rye, which was eat down with hogs. This affords a large coat of straw to be ploughed under, and keeps the ground in a loose, mellow, rich condition. Moreover the corn crop in this rotation is easily worked.

Oats may be substituted for the rye in some of the fields in this rotation. The large Tartary or Poland oat when fed down to hogs leaves as much straw on the ground as rye. Oats bring hogs forward faster than rye, and afford more grain to the acre: these are advantages in favor of the oat. But the oat does not stand up as well as the rye, is soon injured when it falls, sprouts the first rain after it is on the ground and must therefore be fed off very shortly after it is ripe. If oats are raised in considerable quantities for hogs it would be best to cut and get out a large portion of the crop for them, and only allow the hogs to go into one of the fields that was not too large for them to eat up before it would spoil. Even where rye was the principal small grain raised, it would be advantageous to have one field of oats of such a size that it might be consumed when ripe without waste. Where oats has been raised, rye will grow well the next year, if the oats are ploughed under and allowed to come up before the rye is sowed. If the rye is sown on the top of the ground and ploughed under with the oats the first time of ploughing, so many of the oats will come up as to partially smother the rye and do it much injury.

In my trials clover has not succeeded well when sown with the large Poland oat, in consequence of the oat growing so thick as to smother the clover.

Barley from its productiveness and its agreeing well with hogs might be occasionally sown in one of the fields in place of rye.*

Hogs make much manure where they are fattened, and (if they are not fattened in a field) their manure should be hauled out to be applied to the corn crop.

It will be perceived that I have not included the very popular root crops in my rotation upon a farm where pork is the surplus; and I give the following reasons for rejecting them. They are too uncertain.

The turnip is the most uncertain of all our crops. So uncertain, that a good crop cannot be raised more than one year in four. The beet, carrot and parsnip have generally been tolerably certain crops, until last season, when the whole of them were destroyed by the blister fly and the grass-hopper. Even if they were certain they require too much labor at a season when it cannot be spared from the corn crop. Irish potatoes, though free from the last objection, is not from the first. The whole crops were destroyed by the blister fly, (cantharis vitata,) last year.

The only root that I would recommend for its productiveness, profit and certainty upon the pork farm, is the artichoke (helianthus tuberosum,) which is easily raised and very much relished by hogs. The apple orchard is a proper place for planting them. The hogs that are not intended for market may be kept upon them most of the winter; they afford abundance of food and the rooting of the hogs in the fall and winter would destroy many of those insects that are so injurious to an apple orchard.

In parts of the country where mast is plenty the artichoke would be very valuable to be used those years that the mast fails. Should the artichokes not be needed they receive no injury from being left in the ground, as they will continue to grow and increase, and may be saved until from the failure of the mast they may be wanted.

SAMUEL D. MARTIN.

THE FARM AND FARMING OF THE REV. J. H. TURNER—NO II.

For the Farmers' Register.

In a former communication, when treating of a sound economy, that most indispensable appendage to good management, in the hurry of writing, I omitted an illustration which I will now supply. I intended to state, that I keep no overseer. I once had one, but he, though a very honest and respectable man, gave me more trouble than all the negroes put together. I constantly had to do the very things which I paid him to do. It is a very rare thing that the hired man has any eyes except for his own interest. Accordingly, I had to see every thing, and tell the overseer about it, and direct him to do it; and this gave me more trouble than to do it myself.

These overseers, besides, are generally very expensive things. In addition to their wages, their families, if they have any, must be supported. An extra horse must be furnished for the man to ride, and an extra cook for the lady, and an extra cow for the family; and when these, together with the multitude of other nameless *extras*, are taken into the account, the aggregate becomes very formidable in the catalogue of expenses. Accordingly, it is no uncommon thing for the overseer to become rich much faster than the employer. Indeed I have several times known him to acquire a handsome fortune, when the employer lost one. On large estates, it may be necessary in some instances to have an overseer, but in ordinary cases, I do think it would be better to repose the necessary confidence in a faithful servant, and thus invest him with the authority and responsibility of a head man. On small farms there is no doubt on this subject.

Connected with this, I will, with the risk of "bringing an old house over my head," say, that the farmers' *wife* ought in ordinary cases to dispense with her housekeeper. Whilst her husband is his own manager in his proper department, she ought to make her influence felt in all the departments of her proper sphere. Instead therefore of paying another woman to carry her keys, to lock and unlock the meat house, to visit the kitchen or dairy, or to superintend the poultry establishment, she ought to do these things herself. Nor let any active healthy woman (and these are the very women for farmers' wives) feel that in undertaking these things she will encumber herself with over much serving. It is true that these duties, if faithfully performed, will make it necessary for her to stay pretty much at home; but then industry, connected with early rising, and especially a *tact* for business, will make the whole comparatively easy.

I once knew a woman who had a remarkably kind and affectionate husband, but he was an easy "good for nothing" sort of a creature—would sit in the house all day, kiss his wife and caress his children, but would do almost nothing in the way of business. This good man's affairs, as may be supposed, regularly became more and more disordered. His estate, which was at first an ample one, got into ruin, and a heavy debt added greatly to their difficulties. In this state of things, this good man, but bad manager, died. The affectionate widow was almost overwhelmed with sorrow. Here she was left with an estate in disorder, with a family dependent upon her for a support, and with a large debt for which she had to provide, and all this in the very midst of affliction and bad health. At length, when her grief had exhausted itself, she rallied her energies, and showed what she really was. A combination of circumstances now called her true character into action. She mounted her horse, and rode over her farm; the broken down fences

* Last year I sowed a small piece of millet, which produced at the rate of 60 bushels to the acre. I tried some hogs that were in a pen, and they readily ate the heads of it. If this article should succeed equal to my expectations, it will be a valuable article in our rotations upon the hog farm, taking the place of the rye and producing more than double the acreable product. Some, left in the field for the purpose, was found to stand up well and retain its seed in a sound state the whole summer and fall. It produced not only more grain but more straw than any of the small grains that we are using for hogs, and has the advantage that it can be gathered by hogs with less labor than any other grain that we raise for them.

were repaired, order was called out of confusion, and with the aid of a head man alone, the estate was, in a few years, completely relieved from its oppressive debt. This good lady, though now far advanced in life, enjoys better health and spirits than she did in her more youthful days, and all is to be ascribed to her enterprise and industry. Should these remarks meet the eye of this good old lady, I hope she will excuse them. I submit them, not to render her conspicuous, but simply to show what industry and good management, even in a delicate female, can effect.

As another matter of economy, I will mention, that in the various appendages and fixtures of my farm I made it a point, that whatever I got should be of the very best order, and that without regard to the original cost. As an instance of this, I will state, that the cheapest cow I ever owned, cost me when delivered $95. And in purchasing my fine hogs some time ago, I got some as low as $30, but among them, there was one for which I paid at least $120, and this is decidedly my cheapest hog.

And here I will take the liberty to remark, that farmers very often commit a capital blunder in this important thing. They often suppose that the cheapest things are those which cost the least money; whereas the cheapest are those which yield the greatest profit on the amount expended, and at the same time contribute most to our convenience and gratification. Perhaps there is no instance in which this mistake is more frequently and strikingly displayed than in the purchase of land. In this important matter, farmers seem often to lose the faculty of looking ahead, and fix their eye only on the present expenditure. The essential points, fertility, facilities for improvement, and convenience to a good and steady market, together with other things which make land really valuable, are all lost sight of, or are all merged in the sole consideration of a cheap purchase. A little good land in the neighborhood of a good market is worth more, in my opinion, than all the lands of the moon and of the seven stars put together.

My predecessor, as I have been informed, lived on my present farm as long as he could. My old friend, John Carter, has several times told me that his last crop of corn consisted of stalks not larger than his fingers, and he verily believes that it did not yield a peck to the acre. And as I have had occasion several times to make public mention of this gentleman, I will tell the reader who and what he is. Mr. Carter is a plain man, without education, and has sense enough to make no pretensions to it; is a man of close, constant and accurate observation, always experimenting, and would certainly long since have ruined himself, but that he deals in this dangerous article in a small way. In this way he has stored his mind with an exhaustless variety of facts, which his great kindness prompts him to communicate for the information of all. His sole fault is, that he is too prone to draw general conclusions from particular cases. But to return from this digression. My predecessor being thus starved out here, followed the great multitude to the west, where I doubt not he found better land, but I do doubt if he found more substantial means of improving his condition.

This land being thus abandoned, remained for a long time (a small part excepted) in what is called the old field state. Some of it, it is true, had strength enough to put up a sweetbrier, a persimmon, a young pine, or a cedar bush; but large portions of it were so destitute of cover, that the straggling cattle, in their wanderings, merely passed over it, without stopping to take more than a bite or two. In the mean time, I was busily looking out in the neighborhood of Richmond for a small farm, with the view of making it my own. I saw many, but for reasons which it is not necessary to detail, I could not or did not obtain them. At length my eye rested on this forlorn spot. It was in market, and notwithstanding the almost hopelessness of its aspect, I resolved on a purchase. In the midst of the many discouragements with which it was surrounded, there were however some redeeming circumstances, which went a great way towards reconciling me to it. Its position, for instance, was in that direction from the city in which improvement was making the most rapid progress. It was situated on a good and level road, so that access to it would at all times be easy. Its surface was neither so hilly as to subject it to washing, nor so level as to retain large quantities of stagnant waters. Besides, when I came to examine the land itself, it was not so desperate as its first appearance indicated. It is true that a considerable portion was low, lying along both sides of three branches which passed through it, nearly the whole of which was a cold, tenacious pipe clay. But the remainder, which was far the greater proportion, was a light silicious soil, firmly imbedded on a strong red clay foundation.

These then are the materials on which I commenced my operations. In the details, I have perhaps been too particular, but I thought it necessary to be thus minute, that the reader might have a distinct view of the whole subject. And now the absorbing question with me was, how I could most speedily, and at the same time economically, bring these desolate lands into a state of profitable cultivation. To plant or sow them in their present state was a folly of which even a tyro would not be guilty. In this emergency, I had almost no assistance except my own reflections, aided by the little experience I had acquired in my very early youth. At that time (15 years ago) Liebig had not written his 'Organic Chemistry,' in which he sets forth the great value of ammonia. I had never even heard or thought of humus, nor guano, nor poudrette, nor urate, nor bone dust, nor any other of the "*multum in parvo*" manures of which the books treat at the present day. If the editor's invaluable 'Essay on Calcareous Manures' was then in existence, I had not seen it. But in the midst of my want of information as to other and better means of improving lands, I was satisfied of the great and certain efficacy of rich putrescent manures. This was then my resource, and I availed myself of it with all the means in my power. In the beginning, as might naturally be supposed, I made many mistakes in the use of this article. For instance, I used it in the drill, when I ought to have applied it broadcast, and I immediately covered it with the plough, whereas I am now convinced that I ought to have left it on the surface. But amidst my blunders, I conceived the idea of making all the manure I could at home, and then

of adding to it all in my power from town; and this I am sure was no mistake.

The reader is now in possession of the chief material by which I have brought my farm to its present fertility. The quantity used at first was about 50 cart loads of 25 bushels each to the acre. This materially improved the land, as the crops clearly indicated. But I could plainly perceive that there was an evident falling off in the second, and especially in the third and fourth crops. This made a second manuring necessary; and I am now convinced, that excessively poor lands, such as mine were, cannot be made permanently rich under *three* distinct manurings. These several applications ought to follow one another at intervals of about three years. I find that land managed in this way will regularly furnish a crop every year, and at the end of nine years, have so much fertility as greatly to aid itself, by the rich luxuriant vegetation with which it is clothed. Subsequent cropping will make additional manuring necessary, but then half the original quantity will be sufficient. Our small farms, brought to this fertility, and regularly treated in this manner, will furnish a crop, according to the season, *every year*, and so far from deteriorating, will constantly improve; and this I call the "*ne plus ultra*" of good farming.

But there is another article, which I have used to a considerable extent, and with most decided advantage in enriching my farm; and that is the coal ashes. It was observation, and observation alone, which induced me at first to resort to this substance for the above purpose. I had never seen nor heard of its being used for any other object than that of stopping a ravine or of making a foot path to cross the muddy streets of a city. But I had remarked the Jamestown weed and other rich vegetation growing in the most luxuriant manner, around the edges of heaps of this article deposited in gullies and other very poor places. Doctor Tazewell, also, from whom I made my first purchase, in sending for wood from his lot, had been in the habit of carrying out coal ashes and depositing them on the poor places. There also I had the most striking evidence of their fertilizing properties; for all around the edges of these little mounds the green-sward had formed a strong and close turf. With this evidence before my eyes, I could not resist the conviction, that this despised and neglected thing was a valuable manure. It also occurred to me, that my white livery lands were the very place to apply it. Accordingly after grubbing and otherwise preparing these low places, in which I had a deal of labor, I began to cart on the coal ashes. And here it is ludicrous to tell what a subject of ridicule I speedily became among my sapient neighbors. My carts were sometimes stopped, and the question seriously asked, "Can your master be in his senses, in carrying out that useless thing?" I however persevered, and the very next season I reaped as luxuriant a crop of grass, from this poor cold livery land, as I ever saw grow on the rich bottoms in the upper country. The tables are now completely turned, for I frequently detect my neighbors in committing the same folly, for which they heaped on me such a load of ridicule.

There is also another circumstance which highly recommends the coal ashes as a manure, and that is, that they are not only speedy, but *permanent* in their effects. How long they will last, and still manifest their efficacy, I cannot tell. I can point to places on my farm which were enriched by them ten years ago, and these places are rich still. Every time I plough I bring up portions of these ashes, and they appear as fresh as they were when first applied. Whether they have the faculty of fixing other manures in the soil, I cannot tell; but this I know, that they have the wonderful faculty of fixing themselves. From the fact of their exceedingly slow decomposition, one would suppose that they had but little, if any, efficacy. But when I see those places on which they have been deposited, closely covered with a strong turf, I must conclude that there is a powerful influence at work, though I cannot understand the mode of its operation.

Encouraged by my success on the cold livery lands, I determined to test the value of this article on the higher and lighter lands. And here the experiment was equally satisfactory. On a part of a field which I cultivated in corn I applied putrescent manures; on another part, lying along the side of it, I applied coal ashes. The season, especially the latter part of it, was rather a bad one for corn. About the time of earing, it was attacked with a drought, from which the crop suffered severely. But I could but notice the striking difference in the two portions of the field. Where the manure was applied the blades fired, and the product was indifferent; whereas, where the ashes was put, the corn maintained a vigorous green even to the lowest blade, and the crop was a heavy one.

But the chief value of this article is as a top-dressing on the grasses. Here its uniform action is as a charm. Last spring I had the pleasure of a visit from a highly valued friend from the upper country. This visit, as he said, was to the farm as well as to me. After passing over several fields, I conducted him to one which had been covered with ashes the preceding winter. And here he expressed his utter astonishment, declaring that he had never seen any thing to equal it, except under the strong influence of gypsum. I ought to observe, that this field had been seeded to timothy and herds-grass, but there was a considerable sprinkling of volunteer clover among it.

There is, however, one great drawback to the value of this article, and that is its great weight. When sobbed by the rains of winter, (and most of it is in this condition,) 12 bushels is a good load for an ordinary team. Indeed my mules often suffer very much under their task of three loads per day to the distance of about three miles. Upon the whole, I am so thoroughly convinced of the enriching qualities of coal ashes, that could I find a bed of them on my farm, I should feel myself amply compensated for the want of the richest marl.

But the editor has thought proper to read me a short homily on my neglect of lime. On this I have a word or two to say. And, first, I thank him for his remarks. I receive them in the spirit of kindness, for this I know is the spirit in which they were made. But let us inquire wherein consists the great value of lime as a manure? And here perhaps I may advance some things which will deprive me of the good opinion which it seems that Dr. Dupuy and others have formed of

my mode of farming. If this be the case, I shall sincerely regret it, but shall, notwithstanding, proceed in my own simple but candid way.

No one, then, as far as I am informed, pretends that lime is an *enricher*, or that it has one single enriching quality. The early opinion was that it acted as a stimulus, strongly exciting a plant to seek for all the food that might be in its reach. But this opinion is now, I believe, pretty generally exploded; and the more modern phrase is, that it is chiefly useful in *fixing* the manures in the soil, and thus rendering them permanent. This, if I understand him aright, is the idea which the editor intends to convey in his note. Now in this I do most cordially and fully agree with him, and I do contend that my practice has been uniformly in accordance with the same. The editor, and all the advocates for lime, will admit that manure or vegetation of some kind is necessary as a *preparatory application*. No one, at the present day, will think of applying lime to a naked soil. But the first effort is to charge the soil with vegetation, and then the lime will have something to act upon. Now I have been doing this very thing ever since I became a farmer. My land, as I before stated, was perfectly naked. It would not do to resort to lime, whilst it was in that state. It needed manure, it needed a cover, it now has both; and now, and not till now, was it in a state to receive lime.

But it seems that manure will not be permanent unless it has been *fixed* by lime. This, I confess, I do not thoroughly understand. My idea is, that the manures fix themselves. The reason why they are not permanent, is because there is a deficiency in the supply. Make the supply ample, and I will guaranty that they will be permanent. In accordance with this, we see that in cases of great fertility the crop is uniformly a large one. Now let this crop fall and rot on the land, and thus keep up the necessary supply, and the consequence will be, that fertility will not only be permanent, but will actually increase. In forests, therefore, where the whole product is deposited, and nothing is taken off, the lands are in a state of continual progressive improvement, and that too without a particle of lime to fix the manure.

But it will be said that, according to this, the purposes of cultivation will be defeated; that the object of tillage is not merely to keep up fertility, but to obtain supplies for the other necessary purposes of life. This is all granted, and at the same time I maintain that, where the products are regularly removed from the land, depreciation will necessarily ensue, unless other vegetation is furnished to supply the deficiency. Lime alone, without other enriching substances for it to act upon, will not answer the purpose. "The one thing needful," then, is not lime, but enriching vegetation, to make fertility permanent. I will now inform the editor that, some time ago, I did use lime to some extent. My first experiment was with burnt oyster shells, and on a piece of land which had been recently cleared. Here the effects were evident and highly satisfactory. About this time I got hold of the editor's invaluable Essay on Calcareous Manures. Other shorter productions, also, setting forth the great value of lime as a manure, were constantly coming under my notice; from all which I concluded that this was indeed "the one thing needful" as an improver of the soil. A. Robinson, esq., my next neighbor, had also taken up the same opinion. Accordingly we both procured lime, and without regard to any previous preparation, made our applications with the most confident expectations of success. But mortifying to tell, our efforts were without any beneficial effect whatever. We had expended our money and labor, both to a considerable extent, and our only reward was mortification and disappointment.

In connexion with the above views, and going a great way towards confirming them, I will state that I lately made a visit to Mr. F. Staples, who is one of my most industrious and enterprising neighbors. I found him, just where I like to see every young and healthy farmer, in the midst of his negroes, not sitting on a stump, indulging his own indolence whilst taxing their exertions, but actually holding the handles of the plough and taking his full part in the labors of the day. Whilst there, besides several piles of manure which were deposited in his field at convenient points for his crop, I observed a considerable quantity of oyster shells, some already burnt, and others in a situation ready to undergo that necessary operation. I ought to inform the reader that, for two years or more, Mr. Staples has been in the habit of making considerable use of this article on his farm. And here I could not but be struck with the remarkable coincidence, that without any previous observation leading to the remark, this judicious manager, pointing to the lime did say, "I have been greatly disappointed in that article." Having been disappointed myself in the same manner, I was at no loss to explain the cause of his failure. It was simply because his land was not prepared for it. It needed the great prerequisite, *manure;* and all doses of lime administered in this state, instead of curing the patient, did but aggravate the malady. Here then is a distinction which I think of paramount importance, and I hereby give it all the prominence of which I am capable. By not attending to this distinction, I am fully convinced that much mischief has been done, and the only way to counteract the evil is to arrest it at once. How much my neighbors and others may have suffered in this way I cannot tell, but in my own case I am confident that $100 would not cover the loss. The editor, therefore, and all others who are so earnest about *fixing* manures with lime, will see to it, that the manures are in the land *before* they attempt to fix them.

But it will be objected, that according to my own account of the matter, one experiment in the use of lime was a successful one. To this I reply, that this only confirms the position taken above. It will be recollected that this experiment was on land newly cleared. Here there were many small roots and other litter for the lime to act on, without which, I hesitate not to say, there would have been the same disappointment as in the other cases.

And here perhaps I ought to conclude, but still I am unwilling to stop, fearing that I may not have been fully understood, and thus may draw upon myself the animadversions of others for sentiments which I do not entertain. I do therefore candidly state, that whilst I regard lime under some circumstances as a most valuable article, I do at the same time consider it a most

dangerous one, especially in the hands of the inexperienced. We now know that it is a most *caustic* thing, but we did not know it till we had first burnt our fingers with it. And as no one is disposed to blame himself, but if possible to fix it on others, we are disposed to give a portion of the blame to the editor, who, by representing it "as the one thing needful," has unintentionally induced some of us tyroes to inflict this injury on ourselves. In my next, (unless I have to defend myself from the attacks of others,) I shall detail my course of cropping.* J. H. TURNER.

THE FARM AND FARMING OF THE REV. J. H. TURNER—NO III.

For the Farmers' Register.

In the last number I promised to detail in this my course of cropping. But I must beg for quarters a little longer, whilst I take another slight excursion on my favorite pony, *economy*. And at the sight of the word *economy*, the reader will probably exclaim, "Monsieur Tonson come again!" But with the risk of this, I must say that a well regulated economy is one chief branch of agriculture, so much so that no treatise on the latter can be considered as any way complete, without an important bearing on the former.

I would then state, that in the several purchases of my land, negroes, stock and other things connected with the fixtures of the farm, I made it a rule to carry out the principles of Jack Randolph's "philosopher's stone—pay as you go." To this rule, I rigidly adhered, until I conceived the idea of building the house in which I now reside. Up to this time, I had boarded and lodged in town, but I spent every day at the farm. By this time, I had become so interested in the farm, in its improvements, crops, stock, &c., that to spend the whole day there did not satisfy me. I wished also to spend the night there, and to have my family with me. The air, the water, the scenery and the whole routine of employment were so much more congenial to my taste, than those of the town, that I longed to have my family at the farm, that we might fully enjoy our country employments. This made a house necessary. But here was the difficulty: I had by this time so exhausted my little fund, in purchases and various improvements, that I had almost none left for the proposed building. In this state of things, I had concluded to postpone the comfort of a house, until I could command the means to build one. But a kind friend, learning my wishes in this matter, generously offered to furnish the necessary funds. Build, said he, such a house as you choose, and draw on me for the cost, and pay me when convenient to yourself." Now here was a kind offer, which almost any one would have felt himself warranted in accepting. I *did* accept it, but in doing so, I involved myself in difficulty in several particulars.

Hitherto I had dug all my money from the ground, and every dollar came to me moistened with the sweat of my face. But now money came to me in large sums, and it came so very *easy*, that I was tempted to build a much larger and a much more expensive house than a plain farmer's family, such as mine was, had any need of. I invested therefore in a house a considerable sum, which it would have been far more to my interest to lay out in enriching my lands, and in other more profitable improvements. I now have a comfortable house, it is true, but I have it at the expense of a considerable unproductive capital, and this is by no means a comfortable reflection. In the mean time, after the bargain was concluded, and such progress made that it would not do to abandon the undertaking, my friend died, and I was left to make such other provision as I could.

Nor is this the only evil growing out of this mistake. I constantly felt myself fettered and hampered in all my operations. A debt to a considerable amount had been contracted, and during its pendency, I felt it my duty, (not to suspend payment as the banks have done, but) to suspend all the improvements, and indeed all other expenses, which were not absolutely necessary. But I record the fact with gratitude, that this harassing debt is now paid off, and that I "owe no man any thing but to love him." Hereafter it is my purpose to cling to Roanoke's philosopher's stone, with a tenacity which nothing but death can sever.

Perhaps I ought to apologize for this long and minute detail. I can truly say that, in making it, I have no selfish end in view. I hold myself up, in this prominent manner, as a beacon of warning to other farmers. Debt is at all times an exceedingly inconvenient thing. It is a very easy thing for one who has credit to *contract* a debt, but it is exceedingly difficult to *pay* it. A countryman some time ago in Richmond asked a citizen, who happened to be deeply involved at bank, and felt all the pain and inconvenience of his situation, "Sir, will you have the goodness to show me the way into the bank?" Pointing out the way with his finger, he replied "That is the way, sir; but I can tell you, friend, it is much easier to find the way *in* than to find the way *out*." This good citizen was an honest but unfortunate man, and as such spoke feelingly on the subject. I too can speak feelingly; for I can truly say, that in

* We shall be gratified if Mr. Turner will state particularly the mode and circumstances of his application of lime. We have entire confidence in all his statements of facts, and of course, in the want of any manifest operation, and of profitable success of the application. Still, such a result as total failure, or loss, if of judiciously conducted liming, is altogether opposed to general experience; and in the absence of all knowledge of the details of the experiments, we must suspect that there either existed some peculiar obstacles to the operation of the lime—or that benefit really was produced, but so late, that it could not be distinguished separately from the greater effects of the subsequent heavy and repeated applications of putrescent manures. We shall be glad also to learn Mr. Robinson's opinions as to what he may suppose was the cause of his failure, and whether there is any ground for our supposition expressed above. We will submit some comments on Mr. Turner's general opinion on liming; but not until his own views have been fully presented, and completed.—ED. F. R.

all the debts I ever contracted, I found money plenty and cheap; but when I undertook to pay them off, I found it scarce and difficult to obtain: *paying* a debt is always up-hill work; it is a hard row to weed, try it who will.

I will now go further and say that, as a general rule, no farmer ought ever to fetter himself with debt. No man has a right to make a slave of himself, and this every man does who contracts an unnecessary debt. Hence it is that the present is a time of peculiar distress. Go where I may, I meet with long faces, and hear complaints of hard times. And who is it that is in such distress? It is the debtor, and the debtor alone. Where there is no debt to weigh him down the farmer is in comfortable circumstances. His crops for several years in succession have been good, and the prices obtained remunerating. Merchants tell me, that such is the nature of their business that they cannot avoid debt. It may be so; but then they, in common with others, cannot avoid another thing, the thousand vexatious shifts and contrivances, called "*raising the wind*," to which they constantly resort to pay them off.

And now I hope that it will not be considered as an improper departure from my present undertaking, if I arraign and expose some of the intolerable evils under which we farmers are now laboring. And this I do not as a whig or democrat, but I do it over my own proper signature, as an oppressed and aggrieved tax-payer. If any responsibility be incurred, I hereby exonerate the editor and every body else, and take it upon myself alone. At the same time I believe there is independence enough in the press of the Farmers' Register, to incur every responsibility where the honor of Virginia is concerned. And here, without intending to flatter the editor, (I would not insult a high-minded man with a thing so fulsome,) I must say that Mr. Ruffin has received a very unworthy return for the valuable services he has rendered to his country. This then is the first charge that I make, that the farmers, yes, I am sorry to say, the *farmers* have not appreciated the services of the editor as they ought to have done. He saw and felt a great and sore evil inflicted upon the community by the banks, and he had the firmness and independence to arraign it; and because he made use of a farmer's work to tell the farmers their grievances, patronage, I am told, to a small amount, has been withdrawn from him. Now I am no apologist of the editor, nor have I his permission to say one word about his affairs; yet I must in justice to him say, that though he values not the loss of a few subscribers, yet he must feel the disgust and mortification which belong to every high-minded and independent man.* But I have other charges to make to which I proceed forthwith. My next charge then is that the banks have suspended the payment of *their* debts, when they will not allow me to suspend the payment of *mine*. I hold, for instance, a note of the bank, in which they promise to pay me a certain sum. I present it for payment. The reply is, perhaps in an insulting manner, "we have suspended and therefore do not pay our notes." Now suppose this same bank holds one of *my* notes, and on presentment, I tell them that *I* have suspended, not from whim, as in their case, (for they tell us all the time that they are *able* to pay,) but from actual *necessity*. Oh! say they, if that be the case, we shall soon try what stuff you are made of. The next thing is that formidable affair called a protest, the operation of which is to destroy my credit, and thus disgrace me. Nor does the thing end here, but if I have a horse or negro, or even a cow to give milk for my children to eat, the whole goes to pay the uttermost farthing.

I charge further that, in consequence of this suspension of payments, money, or rather bank notes, are made of unequal value, so that if I get a draft on a *paying* bank, I lose my *bread* in the operation.

---

* Our much esteemed correspondent is not mistaken as to the fact of the injurious operation of bank influence, through its bought tools and slaves, on this publication; but he is greatly mistaken if he supposes that the amount of injury from that source, malignant as it may be, would alone be of much detriment. If *that alone* were all that opposed the success of the Farmers' Register, the editor might well disregard all effects of such influence of swindling banks and the fraudulent banking system of Virginia, as much as he despises all the hatred and malice of the individuals who are either so base or so duped as to be thus directed by bank rule and influence. The great and unceasing and all-important obstacle to the proper maintenance, and consequent full measure of utility of the Farmers' Register, is the general apathy and want of all public spirit, and *even of enlightened self-interest*, by the agricultural community of this state. The proportion of the agricultural class of Virginia is amazingly small, who participate in the generous feelings expressed above by one who merely feels and thinks as every member of that class should do, and would do, if true to their own and their country's best interests. The pecuniary support afforded to this publication has never been enough to compensate the editor for the risks and losses necessarily incurred; and for the last few years, there has not been enough of clear profit to pay for a capable clerk. Nearly half the actual support of subscribers is furnished from beyond the borders of Virginia—and the arrears of subscription now due, and of which the payment is desperate, amount to more than all the clear profit ever derived from the adventure. Under such circumstances, the work has been continued less in regard to any hope of its being properly sustained, than for other considerations. But with the close of this volume will end the editor's labors for ten of the best years of his life; and he will no longer obtrude, on the agricultural public, services which seem to be so little appreciated, and which have been so little aided by the sympathy of the great body of the members of the interest designed to be served. In the mean time, his own labors and efforts will not relax; and he trusts that the tenth and concluding volume (under his direction) of the Farmers' Register will be not less valuable than the best of its predecessors.—Ed. F. R.

I charge again, that the legislature, instead of correcting these oppressions, has aided and abetted the same by making it lawful for the banks to commit them, and that this thing has been in operation so long, that it now amounts to an intolerable grievance. But I shall be told, compel the banks to pay, and the brokers will get all the specie and carry it off. To this I reply—let the brokers get it and carry it off. It will even in that event be put no further out of my reach than it now is. As to all practical purposes, the specie might just as well be in Guinea, or in the moon, as in the Virginia banks. In either event, it is where we farmers can get none of it.

I charge, further, that the legislature is ruining us by their immoderately long and expensive sessions. The last legislature was in session a hundred and ten days; the present a still longer time. Now let it be borne in mind, that every day thus spent costs us tax payers, including all expenses, nearly or quite $1,000. We pay therefore, annually, for legislation, upwards of $100,000; and what do we get for it? It amounts to simply this. Our laws are regularly overhauled, some are made and then amended, but finding that they are worse than before, they are *un*-made and then made over again; and this making, unmaking, and re-making, together with a great many long speeches, consumes a vast deal of time and money. Indeed, *speeches* are nearly the only palpable thing that they do make; and how much the speeches are worth every man will judge for himself.

I charge that this legislature is extremely tender of all expenses except their own. As an illustration, I state that a number of poor clerks have been docked 10 per cent. in their salaries, whilst the legislators did not dock themselves one single copper. It is true that a solemn farce to this effect was acted by the present legislature. But what was the issue? I am mortified as a Virginian, when I am obliged to say, that a great majority in both houses, when brought up to their fodder, started back from the rack.

I charge that a great portion of the clamor and noise made by the legislature, about retrenching expenses, is nothing but a solemn mockery. Some time ago, they spent a whole week in trying to make a senator, and after squandering away so much time and money, they adjourned, and no senator was made. This session, they spent three whole days, and of course $3,000, in making a governor, but the state is still without its governor. At another time, they did make a judge, whose salary is $2,500, but it cost our economical legislature three whole days of hard speaking and voting, and the state $3,000 to effect it. Now, if the legislature did really wish to retrench expenses, why deal in such small fry? Why seize upon poor clerk's wages, and make them still poorer? Why not reach forth a strong hand, and throttle the monster at once! Why not adjourn at the expiration of thirty days or less, pocket their money with a clear conscience, and go home to their wives and children, and mind their own business?

I charge, lastly, that this same body has lost nearly every feature of that primitive simplicity which once so nobly characterized a Virginia legislature. The time *was* when the legislature had its pious chaplain, and those great men, John Marshall, and James Madison, and Patrick Henry, and every other member of that day, were not ashamed to be seen upon their knees, humbly asking wisdom from the GOD of wisdom. When I see men thus engaged I can easily believe that they are in earnest. They meet in legislative assembly, not to exhibit themselves—not to carry any party point, but to do the business of their constituents, and then go home.

Now as we can expect no reformation in the banks until the legislature compels it, no more can we expect any reformation in the legislature until the people arise in their majesty and demand it. It is for this purpose, that I, an aggrieved sufferer, have performed the painful task of writing the above. Located as I am, near the legislature and the banks, I see a great many evils which fall not under the observation of the more distant farmers. I have waited so long, that my patience is now exhausted, for a more competent person to take this matter in hand. As no one has come forward, I have reluctantly resolved to apply the trumpet of alarm to my own lips. I have condescended to no personalities, I have sought no man's disgrace, I have sought for reformation, and reformation I will have. It is probable that I shall not stop here; but through our agricultural societies and agricultural papers, shall continue to sound the alarm until there go up one universal shout—*reformation! reformation!*

At the beginning of this paper, I begged for quarters whilst I took a *short* excursion on my favorite pony, economy; but the jade has proved herself of much better wind and bottom than I had any idea of. She even ran away with me. I have now come fairly to the end of my course; whether with safe bones remains yet to be seen. And now for the matter in hand.

In my course of cropping I aim at no wheat nor tobacco. My farm is too small for the former, and the latter I consider too troublesome to be remunerating. In attempting these crops I should moreover meet with competition from all the farmers within fifty miles or more of my market. In determining on a main crop, therefore, it has been an object with me, to fix on that one in which I could most nearly enjoy a monopoly. And as hay is a bulky article, compared with its weight and price, so much so that it will not bear transportation to any considerable distance, I have made that my chief crop. All my farming operations are therefore subservient to the cultivation of the grass crop.

In looking back to the time when I commenced farming, I think it a little remarkable that, without any previous experience to guide me, I should fix on the very crop which, upon trial for fifteen years, I am still convinced was the very best for me to cultivate. I had observed that but little hay was brought to market from the neighborhood, and that most of that little was of very inferior quality. Mr. Porter and others, who were then in the habit of keeping large numbers of horses for the stage and other purposes, depended almost entirely upon the north for their supplies of hay. This was a matter of necessity with them, for the country supplied perhaps not one twentieth part of what was needed. Observing this, I concluded that if I could succeed in raising hay of a good quality, I should have no difficulty in finding a market for it. Nor in this

have I been disappointed. I have never in any instance failed in disposing of my whole crop, and generally at fair remunerating prices. Even at this time, when every body is complaining of the scarcity of money, hay commands a more ready and a better price than almost any other article.

Some of my neighbors have expressed to me the apprehension that the market would soon be overstocked with this article, and that therefore the price must go down. I entertain no such apprehension. The first effect arising from the increased quantity at home will be to arrest the importation from abroad. At present there is still coming a considerable quantity from the north. As long as this is the case, I have no fear that *good* hay will be a drug upon my hands. Indeed, I am pleased to see that vigorous efforts are now making greatly to increase this crop; and I hope the time is just at hand, when, in addition to our neighborhood supplies, we shall see large quantities borne to market on our canal and rail-road. It is quite time that Virginia should assert her own proper independence. She has been dependent long enough, and far too long, upon the north for her hay, and upon the west for her pork.

But the main point remains yet to be touched: what is the *value* of this crop? I answer, that I know no crop which upon the whole requires less labor, is more certain, and at the same time yields a fairer compensation. The chinch bug and Hessian fly, which prey upon our corn and wheat, never touch this crop; nor is it subject to the depredations of any other destructive insect. Give it rich land, well prepared, and a moderate degree of moisture, and this is all that it asks. If, therefore, it be subject to fewer casualties, and when produced commands a fair and ready market, I must pronounce it a good crop. But besides these recommendations, there is another, which in my opinion greatly enhances its value, and that is that I regard it as less exhausting than most of our other crops. I pretend not that this, in common with all other crops that are removed from the land, is not an exhauster; but then it ought to be recollected, that other crops, such as corn, wheat, oats, &c., when removed, make no effort to recruit themselves. They leave the land, with the exception of a little stubble, entirely naked. This is not the case with the grasses; for besides the stubble, they begin immediately to renew themselves, and continue doing so until arrested by severe frosts; so that the aftermath, especially in clover, is often equal to the first crop. This second crop falling, as it does, and rotting on the ground, must contribute materially towards repairing the exhaustion of the first crop. And this, in my opinion, is the true reason why grass exhausts less than other crops. In this view of the subject, I am greatly strengthened by Liebig, and other celebrated writers on the subject of agriculture. They say, and I think with much plausibility, that the very best manure for any particular species of vegetation is that which is derived from itself. Leaves, for instance, is the best manure for forest trees, and wheat straw for growing wheat. If this be the case, then the second grass crop, containing as it does the materials of the first, must be a valuable manure for itself; and this, I think, is a strong argument for banishing cattle and all other depredators from our fields. But more of this hereafter.

As to my mode of cultivating grass, and the peculiar grasses which I prefer, there appeared in the last (February) number of the Farmers' Register, an essay on grass culture, which, were it not that it contains signs of evident haste, I should be disposed to adopt as my own. Indeed I will refer to it, as unfolding pretty fully my views and preferences on the subject. I think it therefore unnecessary to add another word on this point.

But besides grass, which I regard as my main crop, I also cultivate corn and oats, and of late I have turned my attention considerably to the beet and turnip crops. All these, however, are principally for home consumption. If I have any surplus, that of course goes with the grass to market. There is one exception to the latter remark, and that is the corn. I never sell, *directly*, an ear of corn; for by it I support another crop, which, till better advised, I must think a profitable one: I mean my hog crop. And here, without entering into the minutia of detail, I will merely state, that according to the best estimate I can form, the matter stands thus—when corn sells at 60 cents the bushel, and pork at $6 the 100 lbs. (which I consider as a fair average for both,) by turning the former into the latter, I get 90 cents the bushel for my corn. Of course when corn is dearer, or pork is cheaper, my profits are proportionably less. But at the usual average price, I consider myself as getting 50 per cent. more for my corn. I ought also to state, that in arriving at this result, I have to be studiously attentive to other circumstances, such as a thrifty breed of hogs, the care that is taken of them, and the constant economy of their feeding. Now when any farmer can make up his mind to be *personally* attentive to these things, I hesitate not to say that he will find his hog crop yielding him a fair profit. It is true that the last season was a peculiarly discouraging one. I never knew pork so cheap, and the probability is that it will be many years before it is as cheap again. It is to be feared that many farmers who had engaged in raising pork will be induced to abandon it. This, let me tell them, is the direct mode to raise the article; so that when they are compelled to buy, they will have to pay heavily for it. For my own part, I am not at all discouraged. I have just effected the spring sale of my shoats and pigs, and the profit has been nearly or quite equal to any former occasion. For a fine young Berkshire boar, just eight months old, I received $55.

But I am again trespassing on the reader's patience. I must, however, before concluding, observe that my usual rotation (if I have any at all) is two consecutive years in corn, this followed with oats, and the three next years in grass. This of course takes up six years, and then commences the same routine again. I have no doubt that, at first sight, strong objections will be made to this course, especially as three grain crops are made immediately to succeed each other. But I beg the reader to suspend his condemnation, until I inform him that I have another rotation, and that is a rotation of *manuring*, and this I consider of more importance than any rotation of cropping whatever. On this hacknied subject of rotation I have a theory which is perhaps peculiar to myself, and which, when announced, will probably call forth the animadversions of some who are

wedded to their own favorite opinions. But fearless of this formidable consequence, I hereby inform the reader, that I shall still proceed in my own candid way, assuring him, that all I aim at is the *truth*. But as my paper is already a long one, and I have an increasingly strong objection to long communications as well as long speeches, I will defer till my next what I have further to say on this subject. J. H. TURNER.

ON GAYTING CLOVER.

From the London Farmers' Magazine.

Sir,—Properly securing the clover crop and other artificial grasses is a very important agricultural operation, particularly to those farmers who may reside in a humid climate. Observing what I consider very erroneous opinions abroad respecting the best method to be employed for its proper security, I would respectfully offer a few brief remarks on a short practice in this operation.

On leaving a clay land farm a few years ago, in an exposed and arid situation, where there was no difficulty in ordinarily favorable seasons in securing these crops in fair condition, and removing to a turnip soil, producing heavy crops of seeds, in a close situation and moist atmosphere, the seasons also being very wet and unfavorable, I had for the first three years a very great waste in this description of hay. The fourth year (1839) I had a beautiful crop of red clover, with a little rye-grass; and being again a very unfavorable season, I was determined to take every precaution to secure it without injury. I was advised to gayte or ruckle it (an operation which I will presently describe), as is sometimes practised by the best farmers in this neighborhood, and I believe in some parts of this riding of Yorkshire very generally. The work is performed chiefly by women, after the crop has been severed and laid a day or two to dry on the top: the operator beginning at that end of the swathe which was first cut, proceeds to roll it up by the hands till a sufficient sized sheaf is formed; then pulling from the top end a small band, which is tied round the top part of the sheaf so high as to admit the bottom part being spread out and firmly placed on the ground, in which direction it is left as perpendicular as may be, which concludes the operation. The gaytes should be placed in a straight line between the swathes, which gives it a neat appearance, a well as being placed on the driest ground. If possible, it is better done when the grass is dry on the top, but in precarious seasons I would not hesitate to put it together wet, as it will take far less harm in this way than being left on the ground. The mowers should lay the swathes as straight as possible, which greatly facilitates the operation.

The advantages attending this method are, first, it requires no more labor till it is fit to carry, except, perhaps, an occasional righting up, and at the time of carting a woman or boy to pitch it into heaps for loading, the rakers following; secondly, it effectually secures all the leaves and seeds, scarcely a particle being lost, as happens in wet seasons by repeatedly turning it; and thirdly, there is no season, however wet, in which it will not retain its quality; so much so, indeed, that in 1839 my seeds stood in gaytes for three weeks of almost incessant rain, yet they were at last secured so green and fine, it would have been difficult to say, when using them, they had been at all exposed. It is also the cheapest method, as a woman or strong lad will do an acre a day completely, even if the crop be large.

From the report of the Farmers' Magazine, the members of the Framlingham Farmers' Club will discuss this question again on the 24th May, and if any one of them will give this method only a partial trial, I think he will recommend it to his neighbors as worthy an extended practice, being the most economical, and securing both quality and quantity.

Should you deem these remarks worthy a place in the Farmers' Magazine, I should be obliged by their insertion. I am, Sir, your most obedient servant, ANTI-HAYCOCK.

Hall Garth Farm, Kildale, Jan. 26, 1842.

FURTHER CONTRIBUTIONS TO OUR RESOURCES IN MANURE. STERCORIZED BARK FOR NITROGEN AND PHOSPHATES.

From the Cornwall Royal Gazette.

Sir,—Independent of theoretical or chemical considerations, plain reasoning will indicate that the excrements of animals should return to the soil the refuse of their food; and consequently that as cattle dung is an excellent manure for grass, so night soil should be the most appropriate for corn. And the *fact* long known and acted upon by the Chinese and Belgians, is becoming more and more appreciated and employed in this country, though its value is yet imperfectly understood. It appears from Liebig, that the annual evacuations of one man (1½lb. per day liquid and solid—547lbs.) are sufficient manure for an acre of wheat, and that every pound of urine is equivalent to a pound of wheat, estimating the produce per acre at four quarters, (not too high for fair situations thus manured,) and the annual consumptions at one quarter per man (an over estimate): it results, that the excretions of one individual will supply manure for the consumption of four; so much of the nourishment of the corn is derived from the air. And hence some estimate may be formed of the great increase of produce to be obtained by due attention to the preservation of this article, now drained to waste in such profusion into rivers and the sea. And even in the modes of preserving and using it, by the aid of lime, much of its ammonia is wasted; and it has before been shown, that to the ammonia the corn owes its nitrogen, the element on which we have most to depend for improvement, both in quality and quantity. Lime should no more be mixed with night soil, than with gas liquor; on the contrary, the matters added to absorb the liquid, should have an acid tendency. Gypsum does very well by double decomposition. Peat earth is acidulous enough to fix the ammonia, where at hand; but in large towns, this earth often requires pretty distant carriage. Refuse bark is, however, generally produced in populous places, and is an incumbrance to the tanner, from which he is obliged to contrive various methods for relieving himself; amongst the rest burning, to the great annoyance and suffering of the neighborhood.

But tanners' refuse bark has also enough acidulous quality to fix the ammonia in night soils; and being so generally at hand in populous towns may be employed for the purpose extensively.

Three parts of tanners' bark to one of night-soil (urine included, which is as valuable as any part) will make a stronger manure than stable-dung; and with this further advantage, that the stable-dung requires to be rotted, to reduce the long straws, and kill the undigested seeds it contains; whilst the bark being already short, and the night-soil containing no seeds, it may be carted to the field at once; thus saving the heavy waste in rotting.

In the tan-yard, the bark may be stercorized, by having a privy or two, and suitable corners for the work-people, all made to drain upon the heap; calculating say 1 lb. of evacuations liquid and solid from each individual, per day. and proportioning the bark to it; what is above that quantity being disposed of to other persons, for the same purpose. All the hide wool and glue washings and house drainings should run into the same, which should be roofed over, to keep off the rain, but with open sides to encourage evaporation of the moisture. All the ashes of fires, whether of the works or house, should be added, to help the absorption, and destroy the smell; and by this means a tanner employing 25 hands may turn out 25×3 bark, and say $\times 2$ for ashes and drains; $25 \times 75 \times 50 =$ 150lbs. of manure per day, richer than stable dung, much better for corn, and losing nothing in rotting as not required.

In other places, as private gardens, school grounds, &c., the bark may be procured from the tanner, and added to the privy sink, in rather larger proportions, reckoning the evacuations at 1½lb. per entire day of 24 hours. Much less bark will do, say half as much as the night-soil, making up the quantity with garden mould; but the bark is so much additional vegetable matter, at little cost. It may be thrown in, a load at a time, for the excrement to fall upon; but the ashes should be added daily, so as to lie on the top, and absorb the smell. A long and large trunk should rise from the sink, to encourage evaporation and carry up also the smell still remaining; for although much subdued by ashes, it cannot be altogether destroyed without careful mixture not practicable for such a purpose. In this manner large quantities may be collected.

Peat earth will do instead of bark, as above stated, with the precaution not to throw it in in cohesive lumps, which will not absorb, but as dry and crumbly as practicable. The ashes are equally useful in either case.

J. PRIDEAUX.

From the Kentucky Farmer.

AN ESSAY ON THE IMPORTANCE AND PROPER MANNER OF REARING SHEEP, SUITED TO THE CONDITION OF KENTUCKY.

By Dr. Samuel D. Martin, Clarke county, Ky.

To prove the importance of the sheep, it is only necessary to state that all the men in the state are dressed in the productions of their wool half the year, and the preparation of this clothing gives employment to a large portion of the women several months every year. The amount of domestic manufactures in Clarke county alone, (which are principally of wool,) amount annually to $129,000. Beside their wool they furnish meat that is particularly wholesome and nutritious.

They are also very serviceable in clearing a farm of weeds and bushes, as they feed upon a greater variety of herbage than any other animal. Their manure is very valuable and is more evenly distributed by them over the ground they are fed upon than by any other stock, and has the advantage of having no seeds in it to fill the ground with noxious weeds.

It is believed there would be as great profits realized from sheep on our highest priced land as upon any other stock, and the land would be more rapidly brought into the highest possible state of fertility.

Upon such land I have found sheep to be subject to very few diseases, and very productive.

The males should be kept in separate lots until the middle of October, when one male should be admitted to every fifty females. This will bring the lambs from the middle of March to the first of April.

There should be ten acres of rye sowed for every hundred sheep, and the sheep should be turned upon this rye when their lambs are two or three weeks old, this will produce a plentiful supply of milk and enable the ewe to raise a strong and vigorous lamb. For want of something green for the ewes many lambs are lost. The lamb should be castrated at three or four weeks old, and it is also customary to shorten their tail to one or two inches.

At three months old the lambs should all be separated from the old sheep and kept in a lot by themselves. By weaning them at this age they learn to eat and become fat against the fall, and go through the next winter much better than those that are allowed to run all the season with their dams.

The grazing of the rye will also give the blue grass* a good start in the spring and upon this *good start* in the spring depends the value of the blue grass crop. A piece of blue grass that is allowed to show its seed stems before there is any stock turned upon it will produce twice as much pasturage as a like piece that has stock turned upon it as soon as they can get a little grass off it in the spring. The rye will last the sheep until the blue grass is ready to receive them, and after being upon the blue grass about a month they may be put upon the clover fields where they will find plentiful pasturage until the stubble fields are ready to receive them. These will afford them a plentiful supply of weeds and the different grasses for some time, when they may again be transferred to the clover fields. All this time we are keeping them as much off the blue grass pasture as possible. Now when the stubble fields and clover fields are exhausted the sheep should again be turned into one of the blue grass pastures, where they will find a great quantity of food collected for them which will last them through the winter.

Sheep are healthy and keep fat upon this blue

---

* Green-sward, Poa-pratensis.—ED. F. R.

grass and will want no feeding during the winter, unless there should come a heavy snow upon which a crust should be formed. If that should be the case they should have a regular supply of hay, fodder or oats until the snow is sufficiently broken to get at the grass again. By having several such blue grass pastures and transferring the sheep from one to another their health will be promoted and an abundant supply of winter food be obtained. If sheep are turned early in the spring upon a luxuriant clover lot, especially in wet weather, they are liable to be hoven, which frequently proves fatal. On which account it is best not to turn them upon the clover before the first of June, and even then they should not be turned upon it when very hungry. After the first of June if proper care is taken when the sheep are put into the clover fields there is very little danger of its hurting them.

All that has been said in relation to sheep upon our best lands is applicable to the lands of an inferior quality, still we should have to vary our treatment in some particulars. A large portion of the soil of Kentucky that will not produce *fine blue grass* will produce abundant crops of timothy and clover. We should here have to make some greater provisions for wintering the sheep. Upon some such land orchard grass (Dactylis glomerata) succeeds well; and this will also afford a tolerable winter supply of food and a very early spring supply. But here we must depend principally upon clover and timothy hay, corn stock fodder, oats, and such roots and vegetables as we can raise.

Among the roots I would enumerate the turnip, parsnip, carrot, sugar beet, mangel wurtzel, Irish potato and artichoke.

The turnip is an excellent root from its productivenes and adaptation to winter feeding of sheep, but is too uncertain a crop to be depended upon in this state. The parsnip is a much more certain crop and the improved varieties are very productive and are easily kept through the winter requiring no care nor protection from the cold. The carrot is also easily cultivated and productive. Some of the varieties require to be protected in the winter, others do not. Sugar beet is a tolerable certain crop and easily cultivated, so is the mangel wurtzel; they both require protection and are easily injured by frost.

The Irish potato is so well known that I need say nothing more about it.

The artichoke (*Helicanthus tuberosum*) is the most productive of all the roots that ever I have cultivated; all the stock that I have tried is fond of them; they require no care, staying in the ground from year to year without injury, and are easily cultivated. I plant them in drills four feet apart and two feet asunder in the drills, and work them as I would corn, being careful not to plough deep the last time of ploughing.

Among the vegetables for winter feeding of sheep, pumpkins and cabbages are both excellent. The pumpkins may be stored away for early use in a cellar or root house or even in a fodder stack. And cabbage may be kept all the winter in a fodder stack, or even in a barn slightly covered with shucks or straw.

But it is principally on our inferior and mountain lands that sheep husbandry will be found peculiarly advantageous.

There are in the bounds of Kentucky many thousands of acres of land that can be purchased at prices from five to twenty cents an acre. Some of these mountain lands are rich and all of them calculated to afford abundant pasturage of the most appropriate kind for sheep.

To make this land available, one or two acres should be fenced in and the timber inside and for some little way out all killed, the sheep should be brought up and penned in this every night. By penning five hundred or a thousand sheep in this way in this pen for a month the land will be made very rich, and a week before they are taken out the pen should be sowed with grass seed. I should prefer mixing timothy, blue grass, orchard grass and red clover seed for this purpose. While the sheep are occupying the first pen another should be prepared for their reception the next month. In this way a pen of one or two acres will be prepared and sown in grass every month. Means should be prepared also for wintering these sheep. There are glades in most of our mountain land that have green grass in them all the winter; there is also a large quantity of winter fern, which, with oats, should be raised for the purpose, which will assist in wintering and keeping the sheep healthy. With the assistance of a good shepherd's dog, one man can easily herd and attend to two thousand sheep. These mountain lands are covered in the spring and summer with a profusion of pea vine, which will afford ample provision for the sheep; and when it fails, if the seed is put there they will be covered with clover and other grasses.

There are still a few wolves in the mountains, but they are scarce and easily killed in the following manner. Procure an old horse and kill him on some unfrequented ridge (wolves generally travel on the ridges) and stick holes in his flesh all over his body and put two or three grains of strychnine in each hole. The horse should be killed in the beginning of winter, as he will not decay during cold weather, and the wolves are also scarce of food during winter.

The pens that have been sowed with grass will produce a fine crop of hay for the second year, and this added to a crop of oats raised for the purpose will afford the sheep sufficient food for the second winter. The roots and vegetables mentioned before may also be brought into requisition here; and in good weather the sheep will receive much benefit from being driven every day to the glady valley or to those places where winter fern is abundant. The fencing and penning, and sowing of grass seed should be continued through the second year, and after the second winter those pens will afford sufficient hay to winter the sheep with very little assistance from other sources.

The greatest enemy the sheep have is the dog. I was pleased with a law of some of the eastern states upon this subject. They have a tax upon dogs; and whenever sheep are killed by them, the loss is repaired from this fund.

The shelter for sheep in those mountainous regions is generally very extensive. From Miller's creek in Estill county, as far up the river as I have ever travelled, which has probably been fifty miles higher, it would be difficult to find a place where there was not in two or three miles shelter for many thousand sheep under projecting rocks, and in large open-mouthed caves, such as sheep would readily enter.

Sheep should have a regular supply of salt at all times. Where hay is cut for sheep (or any other stock) it should be salted, as it is much more convenient to give them salt in the winter in this way.

The kind of sheep raised must depend upon circumstances. Where the chief demand is for mutton, some of the larger kinds of sheep may be most valuable, as the Bakewell or Cotswold. This will be especially the case where pasturage is very abundant, for these large sheep require pastures. But where the object is chiefly wool, the Merino or a cross of the Merino and Saxony will be found most profitable. The larger sheep will do better in our rich level lands than in mountainous regions. It might have been supposed that a cross of the Southdown upon our Merino flocks would be very advantageous. And such a cross has been strongly recommended in Kentucky.

But this has not been the result, in the trials that have been made in England. It is said in the Complete Grazier, page 230, that the produce of this cross had "tender constitutions, slow feeding, bad shape, and deficiency in the number of lambs. This new breed has therefore been generally given up in Sussex, and also in Wiltshire, where it has been extensively tried." The wool of the Southdown was considerably improved.

The following account of the different breeds of England is taken from Judge Beatty's Prize Essay upon the Agriculture of Kentucky, published in the 4th vol. Ky. Farmer, page 300:

"England is quite as celebrated for her breeds of sheep as of cattle. They may be divided into the long and short woolled kinds. Of the former, the most noted are the following, and they stand in point of size in the order named:

1, Teeswater wethers, weighing per qr. at 2 years old,		30 lbs.
2, Lincoln,	"	25
3, Dartmoor or Bampton,	"	25
4, Cotswold,	"	24
5, New Leicester,	"	22
6, Romney Marsh,	"	22

"These bear fleeces from eight to eleven pounds in the yolk. The Lincolns bear the heaviest. The Teeswater, Cotswold and Dartmoor wethers average nine pounds each, and the New Leicester and Romney Marsh eight pounds. These breeds all bear very coarse wool, which forty years ago sold in England at 10*d.* sterling (20 cents.) Of the short woolled kinds of native sheep, the most noted are the Ryelands and Southdowns. Southdown wethers average at 2 years old, 18 lbs. per quarter; the Ryelands only 14 lbs. at 3½ years old. They are a small race of sheep, but bear finer fleeces than any of the native sheep of England. The Southdowns are the next finest. Their wool at the period above-mentioned was worth two shillings and four pence, sterling, (56 cents,) and their fleeces average about three pounds.

"The Teeswater are the largest sheep in England, and are prevalent "in the rich, fine, fertile, enclosed land on the banks of the Tees, in Yorkshire." They are supposed to have sprung from the Lincolns, being an improvement of that stock, as regards size, with little alteration to the quality of the wool. They are said to be a breed calculated for warm, rich pastures, where they are kept in small lots, in small enclosures, and supported with food in severe winter seasons."

"The Lincolns of the improved breed are said to be "among the best, if not *actually* the best long woolled sheep in England." The flavor of the Lincoln mutton is superior to that of the Dishley, and is a great favorite at Smithfield. Their wool is from ten to eighteen inches long, but very coarse, being only fit for combing.

"The New Leicester or Dishley (Bakewell) is an improved breed of sheep, which, according to Mr. Culley, "is readily distinguished from the other long woolled sorts, by having fine lively eyes, clean heads, without horns, straight, broad, flat backs, round or barrel shaped bodies, fine small bones, thin pelts, and a disposition to make fat at an early age." Mr. Culley adds his testimony in favor of the "superiority in the fineness of the grain and flavor of the mutton, to that of the other sheep of the *long woolled kind.*" But upon this point other authors do not concur. The author of the 'Treatise upon Live Stock,' says the New Leicester mutton is the most fine *by grain* of all the large *long woolled* species, but of a flavor *bordering on the insipid.*" Mr. Livingston, in his admirable Essay on Sheep, speaking of Mr. Bakewell's improvement of the Dishley stock, says, he was of opinion "that fat upon the rump and ribs was more important than tallow, and accordingly he produced sheep on which it is *there found* five or six inches thick. He further remarks that "his sheep are, on that account, less valuable to the epicure than to the laborer, with whom they, in some sort, supply the place of pork."

The wool of this sheep is the shortest and finest of *combing wools*, the length of the staple being six or seven inches."

The late Mr. Robert Bakewell originated this improved variety, and it is supposed the base of the improvement was a cross between the Lincolns and Ryelands, the latter giving fineness to the wool and grain of the mutton. This breed is admitted "to be the most perfectly formed, and consequently more disposed to fatten quickly, and to contain a much larger proportion of meat on an equal weight of bone." They are said also to be more disposed to fatten than other breeds *of the same size of carcass;* but are alleged to be objectionable because of their "fattening too much, and the mutton, in consequence, becoming less delicate in its flavor than other breeds that require a greater length of time in the process.

The Cotswold variety are also of the fine species of combing wool, and, like the New Leicesters, are said to have derived this feature from a cross with the Ryelands.

The Romney Marshes are a large breed, carrying wool suitable for combing, of rather a fine quality. They acquire their name from the marsh on which they are chiefly raised, and are said to be well adapted to be "fattened on the rich kinds of marsh pasture, and on those which extend from Hastings to Rye in Kent." The author of the "Synopsis of Husbandry" says that "a convincing proof of the great value of this breed of sheep, as well as of the land on which they are fed, is that six to eight wethers may be fattened per acre." This breed

would be a valuable variety, for the flat and marshy lands which prevail in many parts of the north-western states, and which are found in some places on the borders of the Ohio and other rivers of Kentucky.

The Dartmoor or Bampton variety are prevalent in the districts from which they derive their name, the length of their wool is about the same as of the Romney Marsh sort. These breeds have been improved by a cross with the New Leicesters, which it is said "will in some situations bring forward wethers at 20 months old weighing twenty pounds the quarter, with a shear of eight pounds of yolk wool to the fleece." The mutton is said to be of good quality. It should be remarked that in England all the *large breeds of sheep* are raised chiefly *for the mutton*, and that wool is only a *secondary* object. The following statement will give a pretty correct idea of the usual price of mutton in England:

Mr. Dawson, of Buthorp, in the year 1796, sold two hundred *two shear* wethers, (two and a half years old,) at three pounds sterling round. An average of his sales for the six preceding years was as follows: 1790, 35*s.*; 1791, 35*s.*; 1792, 43*s.*; 1793, 38*s.*; 1794, 44*s.*; 1795, 50*s.* These were New Leicesters, which had been twice sheared. If each shearing produced eight pounds, (a large allowance for young sheep,) the wool at 10*d.* would have yielded 13*s.* 4*d.* or 6*s.* 8*d.* per annum. But the average of the sales of each wether during the seven years was 43*s.* 7*d.* Thus the amount received for mutton was six and a half times as much, *annually*, as was received for wool. It will be perceived that the price of mutton gradually rose from 35*s.* to 60*s.* At the latter rate, the *mutton* produced, *annually*, nine times as much as the annual produce of wool. The contrast between the wool and mutton, of the larger breeds, such as the Teeswater, Lincoln, Bampton and Cotswold, would be still more remarkable. It should also be recollected that since the year 1796, all kinds of meat have risen, whilst coarse wool has remained about stationary, and consequently that, at this time, the disparity between the price of wool and mutton would be still greater than it was in the year 1796.

I desire that these circumstances may be borne in mind, when I come to treat of fine woolled sheep and of the sheep husbandry of Kentucky.

Of the various native breeds of *fine woolled sheep* in England, I propose to speak only of the Southdowns and Ryelands. The latter were formerly held in high repute, in consequence of their extreme fineness of wool, but since the introduction of the Spanish Merinoes, (1792,) which far excel the Ryelands in fineness of staple, they have, in some measure, lost their former high reputation. They are, however, considered an excellent stock on which to cross the Merino breed. The half blood from this cross produce a fleece, it is said, averaging five pounds in the yolk, and worth 3*s.* sterling, (72 cents.)

The Southdowns are next to the Ryelands, as regards fineness of wool. Mr. Culley describes this variety "as having no horns, gray faces and legs, fine bones, long small necks, and rather low before, high on the shoulders, and light in the fore quarters, sides good, loin tolerably broad, back bone rather high, thigh full, twist good, mutton fine in grain and well flavored, wool short, very close and fine, in the length of the staple from two to three inches, weight per quarter of wethers, at two years old, eighteen pounds." This breed prevails "on the dry chalky downs in Sussex, as well as in the hills of Surry and Kent." It is said to have been "much improved, recently, both in carcass and wool, being much enlarged forward." They are considered as an excellent sort for less fertile and hilly pastures, as feeding close." They are "hardy, and disposed to fatten quickly." They come quickly to maturity, the wethers "being seldom kept longer than two years old, and often fed at eighteen months." They are also "capable of travelling well and of resisting the effects of exposure to cold." The celebrated Mr. Coke, now Lord Leicester, is said to have the best and finest Southdowns in England."

I have extracted the above from Judge Beatty, but as the author from whom he quotes spoke of the Southdowns of his day, I thought it proper to give the opinions of some later writers upon these sheep, and shall then proceed with my quotation. At present Mr. Ellman of Glynd is "said to have the finest Southdowns in England." The following extract is taken from Blacklock's Treatise on Sheep, written in England in 1838 and republished in the United States in 1841. On page 20, American edition, he says:

"*The Southdown*, like the Ryeland, are, from the delicacy of their constitution, unadapted for bleak situations, but sufficiently hardy and active for a low country; their average weight is from 15 lbs. to 18 lbs. a quarter; that of the fleece, which is very short and fine, being from 2½ lbs. to 3 lbs. They are without horns, have gray faces and legs, a neck low set and small, and a breast neither wide nor deep; their mutton is fine in the grain and of excellent flavor, having been brought to great perfection by Mr. Ellman of Glynd, and other intelligent breeders. They are mostly found in Sussex, on dry chalky downs producing short fine herbage, and arrive early at maturity; in which respect they are equal to the Cheviot, though inferior to them in quantity of tallow. Formerly they would not take on fat until four years old; now they are always at market when about 2 years of age, and many are killed before that period."

From the above quotation it appears that the Southdown sheep of the present day have "delicate constitutions" and are not calculated for "bleak situations," but are well suited for a low country. Neither Southdown, Bakewell or New Leicester, nor Cotswold would suit our mountain lands. The Merino, and their crosses upon our native sheep, would be found to suit our mountains best.

These Southdowns formerly were slow in coming to maturity, requiring four years; what means have been resorted to for producing their early maturity in the present race we are not informed. Whether it was the introduction of some foreign blood or judicious selection and breeding we know not.

It appears that, whatever the means may have been, the constitution has been so much injured that they are not *now* the same hardy sheep they were forty years ago.

A comparison of the mutton of the Southdown with the Merino, in the only case that has come to my knowledge, has resulted in favor of the Merino, and the Merino wool in England brings double the price of the Southdown. In the United States the difference in the price of the wool is not so great, the Merino being worth about forty or fifty per cent. most. The quantity of wool yielded by the Merino is also greater than the Southdown, whilst the quantity of mutton produced by the Southdown is greatest.

I have no practical experience of either Southdowns, New Leicester or Costwold, but believe the Merino, with their crosses upon our native sheep, will be found a hardier race than either of the foregoing, and whilst the relative prices continue any thing like they are at present, it will be much more profitable to invest money in them, than in either of the others.

I shall now resume my quotation from Judge Beatty.

An English writer, comparing the Southdowns and Norfolks (a very noted breed of the fine woolled sort) says "in short, the leading characteristics of the high and full bred Norfolk and Southdown sheep seem, upon comparison, to be chiefly these, the wool of both is found to be of the first clothing *quality*, but the larger *quantity* is produced by the Southdowns; the mutton of both is equally delicious. But the quiet, gentle Southdowns, in the pasture, must be opposed to the wild, impatient ramblings of the Norfolk, whose constant exercise not only excites continual appetite, but at the same time occasions a considerable waste in the pasture, by treading down and unnecessarily spoiling a great deal of food they do not eat."

It is further remarked, that "the hardiness of the Southdowns, enduring wet and cold lodging and a greater degree of abstinence and fatigue than the Norfolk, in the fold, is a superiority of much moment, and only to be equalled by another which they possess, in a very superior degree, which is that of doing well upon coarse and sour pastures." It is added "that the Southdowns, compared with the Norfolk, are equally good turnip sheep; and for every possible purpose, whether for their flesh, for their wool, for breeding, for folding or for the butcher, they demand a less supply of food and of an inferior quality to that which, in every situation, would appear indispensable to the well doing of the Norfolks."

The foregoing statements and facts present a very favorable view of the Southdown variety of sheep. But their merits are still more strongly sustained by a course of experiments, made by the Earl of Egremont to test the relative value of the New Leicester, Southdown, Romney Marsh, and some half bloods, being a cross of the New Leicester and Southdowns. It would occupy too much space to give the whole course of his experiments in detail, but the following is the substance of them. In the month of August he put in the same enclosure, wether lambs of the preceding spring, as follows: 17 Southdowns, 19 New Leicesters, 12 half bloods, a cross of the New Leicester and Southdown, and 7 Romney Marsh. They were all kept alike till June of the following year, when 12 of the Southdowns and all the half bloods were found in marketable condition; and the former were sold at 340, and the latter at 330, sterling. None of the New Leicesters or Romney Marshes were in marketable condition. This experiment shows the superiority of the Southdowns and half bloods, where it is desirable to sell at an early age.*

A part of each kind was kept over for further experiments, and it was found that between June and the 7th of September, (ten weeks,) the Southdowns had gained 13 per cent., the New Leicester 21 per cent., the half bloods 13 per cent., and the Romney Marshes 14 per cent. Here was a gain of 8 per cent. by the New Leicester, and 1 per cent. by the Romney Marshes, over the half bloods and Southdowns. This is naturally to be accounted for so far as relates to the Southdowns, from the circumstance of the two sorts, which had gained, being of a larger breed than the Southdowns. It will be recollected that the New Leicester wethers at two years old weigh 22 pounds to the quarter, the Romney Marshes 25, and the Southdowns only 18. They were now, (7th September,) about one and a half years old, and consequently it was to have been expected that the *larger breeds*, which had fallen back during the winter, should increase more rapidly during the summer, than the smaller ones, in order to attain their appropriate weight at two years old. They were weighed again the 1st of December following, when the Southdowns had lost 3 per cent., the new Leicesters 2 per cent., the half bloods 4 per cent., the Romney Marshes had gained one third of 1 per cent. All the sorts, it will be observed, must have continued to gain for some time after the 7th of September, and the larger breeds, for the reasons here stated, must have gained more rapidly than the smaller ones, till winter set in. At this period all would begin to lose, and the loss exhibited above *was not the whole loss*. What had been gained between the

* This experiment shows that the Southdown sheep bear starvation better than the New Leicester, but is not at all decisive of their earlier maturity under different treatment. Had the sheep been kept so as to prevent them from losing flesh in the winter and sold as soon as they were in condition in the spring, the result would probably have been very different.

We find during the time that they had plenty to eat, from June to September, that the New Leicester gained 21 per cent., while the Southdowns gained 13 per cent. Here it is likely the gain is much greater in the New Leicester than meets the eye. We are told that the New Leicesters are of a larger breed than the Southdowns, of course any per cent. upon a large animal, is much more than the same per cent. upon a small one. Blacklock gives the average weight of the New Leicester at 18 to 26 lbs. per quarter, and their wool at 6 to 8 per fleece. The Southdown is averaged by him from 15 to 18 lbs. per quarter, and their fleece from 2½ to 3 lbs. From the above it appears the New Leicester has 22 lbs. most mutton, and his wool at 20 cents, and the Southdowns 25 cents, which is about the market price of the two, the New Leicester fleece will be found to be worth about double the Southdown in Kentucky, where coarse wools bear relatively a higher price than fine.

For mutton I have no doubt that the Costwold and New Leicester, will both make a better cross with the Merino, than the Southdown: For wool I think neither of them should be used as a cross unless it be desirable to make coarser wool, when the cross with the New Leicester will be found to give double the quantity. S. D. M.

7th September and the period at which they began to fall off, should have been added. If these circumstances be taken into consideration, this experiment would be very favorable to the Southdowns; but the next experiment is still more decisive in their favor. They were weighed again the first of March following, when it was found the Southdowns had lost, between the 1st of December and 1st of March, four per cent., the New Leicesters 14 per cent., the half bloods 10 per cent., and the Romney Marshes 5 per cent. During the second as well as during the first winter, the Southdowns exhibited a decided advantage over the New Leicesters. The Romney Marshes, it will be seen, stand upon almost as good ground as the Southdown, and did much better than the New Leicesters.

The next experiment shows that from the 1st of Dec. to June 19th, the Southdowns gained 13 per cent., the New Leicesters 9 per cent., the half bloods, 9 per cent., and the Romney Marshes 17 per cent. Here again the advantage is decidedly in favor of the Southdowns and Romney Marshes.

The experiment was continued through the third summer, when, as might be expected, the New Leicesters again took the lead; and as the result of the whole experiment it is stated "that the profit for two years and two months feed, adding the value of the wool, was 5*d.* and a fraction per week for the Romney Marshes, and from 4*d.* to 7½*d.* for the New Leicesters, from the time of their being lambed. The former part of the experiment had shown that the Southdowns and half bloods, at the age of 64 weeks, gave 7*d.* per week profit."*

Thus it appears by a course of experiments fully and fairly made, by the Earl of Egremont, that the Southdowns, even for the purposes of mutton, are decidedly more profitable than the New Leicesters. And this result follows without allowing any thing for the *increased quantity of food* consumed by the New Leicesters, or for the *superiority* of the mutton of the Southdowns. It is a well established general principle, that the larger the animal the more food they will require. Here the Southdowns, the smaller animal, upon the same kind of keep, gave 7*d.* profit per week, at the age of 64 weeks, whilst the New Leicesters at the age of 113 weeks, gave a profit of only 4*d.* to 4½*d.* per week. The wool of the Southdowns is also more valuable. Those of a good quality will average three pounds, worth 2s. 6*d.*, (60 cts.) per pound, whilst the wool of the New Leicesters averaged, (ewes and wethers,) about seven pounds, is worth only 10*d.*, (20 cts.) The annual product of the wool of the Southdowns would be 180 cents, and of the New Leicesters only 140 cents.*

I have been induced to go into these details in relation to the merits of the New Leicester and Southdown sheep and of the Romney Marsh breed, in consequence of a strong impression having been made in this state that the New Leicesters would be the best stock for us to adopt with a view to mutton and common clothing wool. I am decidedly of opinion that for both purposes the Southdown breed of sheep would be greatly preferable. The mutton of the latter, in point of flavor, is greatly superior, the wool is every way better adapted to clothing purposes, the sheep are hardier, thrive better in winter, and would suit admirably the hilly regions, which predominate in the eastern, and south-eastern borders of Kentucky.† I am also of opinion that the Romney Marsh breed would be finely adapted to the flat and marshy lands which predominate in some of the new states and which are also found on the borders of some of our rivers.

"The New Leicesters will become valuable when we engage in manufacturing worsted, which will require combing wool, but in the mean time the best of our native breeds, improved by the introduction of the Southdown and Merinoes, will be better adapted to our circumstances and wants.

"I have hitherto only treated of the native sheep of Great Britain. It is wonderful that a people who paid so much attention to sheep husbandry and who were so extensively engaged in the manufacture of fine wool, should so long have totally neglected to introduce the Merino breed, confessedly the finest woolled sheep that existed any where in Europe. This was owing in part to their prejudices in favor of their own Ryelands and Southdowns and partly to an opinion that the Merinoes could not exist in the climate of England, or that if they could, they would so degenerate as to be less valuable than their own native sheep. It was imagined "Spain possessed some peculiar advantages of soil and climate which it would be in vain to look for elsewhere. And it was believed, says a British writer, "that the superior fineness of the Spanish fleeces was derived *entirely* from some peculiarity of the soil and climate." This opinion was so firmly fixed, says the same writer, "that he who asserted the contrary was regarded by agriculturists and clothiers as a speculative theorist, only deserving pity." Yet long anterior to the period when these *notions* were so strongly predominant in England, the Merino breeds had been introduced into Sweden. As early as 1739 "the Swe-

* This experiment would have looked a little more like it had been *fairly* made if the weights of the Southdowns had been given when they were sold, and the weights of the New Leicester the seventh of September when they were ready for market. But to keep animals that were fat in the fall of the year, and let them fall off in the winter and then compare their gain per week with those sold the summer before, looks like any thing but *fairness*.

If the sheep had been kept in growing order all the time, this experiment would no doubt have exhibited a very different result; and the question would not have been which kind would bear starvation best, but which would give most gain for feed consumed. There appears to be something unfair in taking for granted what is not proved, "that the larger the animal the more food they will require." It may be "a well established general principle," when applied to animals of the same family, but even then there will be found exceptions, but when applied to animals of different families, it should never be taken for granted, but should be proved before an argument can be based upon it.

S. D. M.

* These estimates are made in reference to the English market.

In the Kentucky market the New Leicester fleece would bring 60 cents most.

† See quotations from Blacklock, between pages 14 and 15. S. D. M.

dish government, for the promotion of this race, instituted a school of shepherds, under the care of Mr. Alstrœmer, (who first introduced the Merino sheep into Sweden in 1723,) and public funds were appointed for granting premiums to those who sold rams of this breed. These premiums were continued up to the year 1792, when being no longer necessary, they were discontinued.

Merinoes were introduced into Saxony as early as 1765, and they were attended to with such assiduity, skill and judgment, that the flocks of that country, in point of fineness of staple, soon came to excel the finest Spanish Merinoes.

"These examples did not escape the notice of France. In 1776, this celebrated breed of sheep was introduced into that country by Mr. Trandain, intendant of finances, under the direction of the celebrated naturalist, d'Aubenton. This experiment succeeded so well as to convince the government, "that it was easy to introduce and preserve a race of sheep in France, producing superfine wool; and in the year 1786, a selection of 376 rams and ewes, from the finest flocks in Spain, was made and were conducted under the care of a mayor, to the farm of Rambouillet." It was not until after all these experiments, that an effort was made to introduce these celebrated sheep into England. The first efforts were made by individuals in 1787, but the importation then made attracted but little attention, and scarcely excited any interest. "The sheep, however, (says an English writer,) *lived*, though treated in the English manner, and the wool *had not deteriorated*." These facts having proved that the Merino race of sheep could be naturalized in Great Britain, the then reigning monarch, Geo. III., in 1792 obtained from the Marquis of Campoalonjo, five rams and thirty-five ewes of the Nigrette race."

It might have been supposed, now that the sovereign of the country had taken a personal interest in introducing the Merino breed of sheep, that all prejudices against them would have subsided; but such was not the fact. "Although the wool was admitted to be equally fine, with the best wool imported from Spain," yet the manufacturers would not give the same price for it, "fearing that it might not prove equally good when manufactured;" and the king was compelled to have his wool manufactured on his own account, "to demonstrate its fitness for superfine cloth." So slow is the progress of truth in overthrowing *prejudice* and *error*. The merits of the Merino breed finally triumphed over all obstacles, and they are now deservedly held in Great Britain in the very highest repute, both as regards the pure breed and the crosses upon the best English stock. It has been ascertained that a cross of the *best* Merino rams upon the finest Ryeland ewes, requires *five* crosses to produce as fine wool from the mixed breed as from the pure stock. Thus a cross upon Ryeland ewes, bearing wool worth 3*s*. will produce a breed bearing wool worth 3*s*. 7*d*., and each subsequent cross will add 7*d*. to the value of the wool, so that after the *fifth* cross, the offspring will bear wool worth as much as the Spanish, that is, 6*s*. per pound, provided the *rams and ewes* are of the *finest quality* at the *commencement of the cross*. This shows the error of the opinion, that the new Leicester, or any other of the coarse long woolled sheep, will furnish a good cross for the Merino race. Next to the Ryelands, Southdown ewes of the finest quality furnish the best cross of any of the native sheep of Great Britain. The United States not having commenced manufacturing fine wool, at the period when the Merinoes were introduced into England, had not the same inducement to make an effort to naturalize that valuable race. But not long afterwards, Chancellor Livingston, our embassador at the court of France, studying to promote the interests of his country, by all the means in his power, turned his attention to this subject, and in the year 1802, selected "two pair of the finest Merinoes he could," from the improved flocks of France, "and sent them over under the care of one of his own servants, intending to follow them by others."* These, says Mr. Livingston, "were the first couples ever imported into the United States."

Shortly after this period, Col. Humphreys, of Connecticut, introduced directly from Spain, a considerable number of this valuable race. These importations laid the foundation of the Merino breed of sheep, which are now so numerous in the United States. They were first introduced into Kentucky by Mr. Seth Adams, in the year 1809. A small proportion only of his flock were of the full bloods, the balance being the produce of a cross upon the native sheep of the country. Shortly afterwards, Mr. Prentice, Mr. Lewis Sanders, and other spirited gentlemen, introduced a number of the pure blooded Merinoes. In the year 1829, the Hon. Henry Clay imported from the western part of Pennsylvania, a flock of fifty full bloods, being a selection from one of the best in Washington county. These and other importations have laid the foundation of the Merino flocks in Kentucky, and nothing is now wanting, but sufficient attention and skill, in the management of our sheep husbandry, to secure to us a full participation of the great advantages which must accrue to the United States from the rearing of fine woolled sheep."

"The political contests of the day and the selfish views of ambitious aspirants, may for a time depress the interests of agriculture and of *sheep husbandry in particular*, but it is impossible, that this can continue to be the case for any great length of time. When we look at our present population and take into consideration the well established fact, that it increases in a ratio of 33⅓ per cent. every ten years; that our exports except in a single article (cotton) instead of increasing in a ratio with our population, is continually diminishing, when we see the results of our present system, (depending upon foreigners to manufacture for us what we could so easily manufacture for ourselves) a system encouraged and promoted by the legislature of the national government; to the periodical reversions in trade of the most alarming and distressing character, arising in a great degree, from too extensive reliance upon foreigners to supply us with *clothing, blankets, and other necessaries*. * * * When we shall learn wisdom from experience, we shall be compelled (though perhaps not until after long and severe suffering) to do as all wise nations have done before us, protect our *agricultural interest*

* Livingston's Essay on Sheep, p. 9.

by giving protection *to those who manufacture the raw products of our agriculture.* When this period shall arrive, our Merino flocks, as well as those of other races will be found to be of immense value and of great importance to the general interests of the country. Wool to the amount of two hundred millions of pounds would be produced, (if due encouragement shall be afforded,) before our population shall have reached thirty millions, which will happen within the next twenty years, and in ten years thereafter it will probably have reached forty millions."* What vast results, then, are to spring from a proper attention to sheep husbandry! How immensely will the wealth and comfort of our citizens be promoted and the fertility of the soil increased by rearing and feeding 66,000,000 of sheep! But the direct advantages resulting from sheep husbandry will not be all. Other agricultural pursuits will be greatly promoted, first, by diverting a portion of agricultural industry from those branches which have been pushed to too great an excess; and secondly, by the new market that will be furnished for agricultural products, by the numerous class of individuals who will be employed in manufacturing the immense quantity of wool, which the United States are capable of growing. Too much attention cannot be given to this important subject. Fine wool, as well as that of a medium quality, (such as will be produced by Southdowns and a Merino cross upon that valuable stock,) and the product of our native stock will all be objects of much importance. And when the manufacture of worsted stuff goods shall be extensively introduced, combing wool will also be in great demand.

Sheep husbandry is important for three purposes, 1 wool; 2 mutton and tallow; 3 as a means of manuring and fertilizing our soil. I have sufficiently treated of the two first; the third is too important to be passed over in silence. I have heretofore suggested that much manure may be saved by folding sheep of nights. It is doubtful, however, whether the injury to the health of sheep will not be too serious to justify that practice, in warm weather; but in cool frosty weather folding sheep of nights may be safely resorted to. But whenever the practice of folding, for a length of time, in the same place, is pursued, the pen should be kept well littered with straw, [or leaves,] as well for the comfort of the sheep as with a view of increasing the quantity of manure.

It will be most convenient to have the sheep fold adjoining a shelter under which the racks and troughs are placed. The shelter should be entirely open on one side, with a south or south-eastern exposure, and enclosed on the opposite side; with a suitable building at each end, one for hay and the other for roots for winter and early spring feeding until the pastures are sufficiently advanced.* It would be most convenient to have the sheepfold and house adjoining a meadow, on which the sheep should be suffered to range during the day. This will be beneficial to the health of the sheep, and their manure will be saved, and distributed without the expense of hauling. With a view of the like saving of manure during the part of the year in which the sheep are not folded of nights, they should be suffered to range, as far as circumstances will admit, upon grounds intended for future cultivation.

In England it is a common practice to feed off their turnip crop to sheep, upon the ground upon which it grew. This is done by enclosing a small space with hurdles, into which the sheep are put and continued until they consume all the turnips growing within the enclosure; another space is then enclosed and fed off and so on in succession until all are consumed. This is found to be a very convenient practice in England, as it saves labor, both in feeding and distributing the manure, and might be adopted here with great advantage, if, upon experiment, it shall be found that the ruta baga† will succeed well in our soil and climate and is sufficiently hardy to stand our winters.

A species of cabbage, that is sufficiently hardy to stand the winter in England, is frequently fed off to sheep, upon the ground upon which it grew, in the same manner as turnips, and it would be worthy of inquiry and experiment whether cabbages suitable to our climate and soil could not be raised to advantage for feeding sheep, during the short period we cannot furnish them with grass or while the grass is covered with snow.

It is probable that the sugar beet will be found to be a more valuable crop in our dry soils than any description of turnips.‡

---

*" The Albany Cultivator estimates the number of sheep in the wool growing states of the north at 15,000,000."

This estimate I consider greatly too low. The single county of Washington, Pennsylvania, has 1,000,000.

The balance of this note is a table showing the increase of our population from 1790 to be 33 1-3 per cent. for every ten years. This table I deem it unnecessary now to copy. The census that has been taken since our author wrote proves the correctness of his calculation.

The population of the United States is now 17,068,180.

The population of Kentucky is 776,923. S. D. M.

* If the blue grass pastures have been permitted to grow the latter part of the season, they will afford green food all the winter, and upon this and pasture of green rye, the sheep will do better and be more healthy than fed in any other way. These pastures are good all the winter. The sheep should be turned off them the 1st of March to give them an opportunity of producing a good crop of grass. The rye fields, will now support them until the 25th of April, when they can be turned again upon the blue grass pastures. M.

† The ruta baga succeeds but poorly upon my farm. I have raised many crops, and although I have drilled them very early as well as late, and worked them well, I have never raised a crop that were at all to compare with the accounts I have seen of this root.

I thought for a few years that the fault might be in my seed, and procured seed from a great variety of seed stores, yet the result was the same. The ruta baga grows mostly above ground, and will not stand our winters without protection. We have a large turnip that grows mostly under ground that will stand our winters well. Early sown in May has done best with the ruta baga.

‡ The sugar beet is much more productive than the ruta baga, and until last year was a very certain crop. Mine were injured the season before last, but were entirely destroyed last year by a dark-striped blistering fly (Cantharis vitata) generally called the potato fly. Those flies or rather bugs destroyed my potatoes, carrots, parsnips, beets, and cabbage. If these bugs should

The latter are so subject to be destroyed by insects when they first come up ; and are so liable to be injured by drought, as to render them too uncertain to be relied upon as a crop for winter food for stock. The beet crop is much less subject to injury from insects, and will probably be found more productive.

One of the great recommendations of sheep husbandry is that it can be carried on extensively with less labor than any other branch of farming producing the same profits. If blue grass pastures are saved for them, and the quantity of rye before recommended be sown, they will not require feeding more than ten days upon an average in a year, and this feeding may be done with oats, hay, or corn-stalk fodder. Where there is a deficiency of blue grass, other means must be resorted to for the purpose of supplying them with winter food. Rye holds a place with me next to blue grass ; but it is not expected that rye will produce food for a large flock of sheep all winter. I would then recommend that oats, clover hay, timothy hay, and hay from any other grass that the farm will produce be provided in sufficient quantity to winter them, and after this raise as many roots as you can.

In the mountainous regions where caves are plenty the best place to keep those roots that require protection is in one of those caves. Roots will not freeze thirty yards from the entrance of any of those caves unless the mouth is very wide and high ; and if that should be the case put them in a little farther.

Roots keep well buried in the ground, about fifty bushels in a place. They should be laid on the surface and piled up as high as they can be, and have leaves or straw put over them, and be covered by throwing on a foot of earth. A stick two inches in diameter should be stuck in the top of the pile and after the dirt is put on, tread the dirt around the stick, and pull it out, and have a little bundle of straw large enough to fill the hole, and put it in it. The straw or leaves will prevent the roots from getting dirty, but they will keep equally as well without. In England rape is very much used for the purpose of feeding sheep and enriching the land. It supplies a rich and very fattening food for sheep the latter part of summer and in the fall. It is particularly serviceable in fattening those that are for sale, and preparing those that are kept, for passing better through the winter. An acre of good rape will last one hundred sheep ten days. Experiments should be made for the purpose of ascertaining whether rape be suitable for our soil and climate. If it should succeed with us, it would be particularly valuable in enabling us to save our blue grass pastures for winter use. It is generally sown on the poorest ground, which it speedily enriches. But it will grow better upon rich ground. A few acres are fenced off for them at a time.

The climate of Kentucky is particularly congenial to sheep. When they can have green food all winter, they are subject to scarcely any disease. When confined and fed upon dry food they are not so healthy, and great loss of lambs is sustained by those who have nothing green for their sheep during the suckling season. Sheep bear confinement worse than any other of our domestic animals.

Although I have said above that where blue grass pastures can be obtained that sheep will not require more than ten days feed during the winter, yet I would recommend that provision be provided for feeding them two months. Each sheep will eat about two pounds of hay a day.

I would recommend that the hay for the sheep be stacked in the meadow where it was cut in the following manner. Plant a smooth pole from 6 to 10 inches in diameter firmly in the ground, and around this make your stack of hay, beginning small and swelling very much to the middle and then tapering again to the top. As before observed salt should be sprinkled on whilst building the stack. When the ground is covered with snow so that the sheep cannot get grass, they should be turned into the meadow which should also have water in it. A spring should be included in the meadow, if possible, as it would afford them a constant supply of water, without breaking the ice, which accumulates so fast upon our ponds and streams, that although it may be broken three times a day, still, in extreme cold weather, the stock will suffer for want of water. I would recommend that shelters be formed in the meadow in the following way. Build a fence by placing each rail upon the other at right angles, so as to form pens thus :

these pens should be covered with cornstalks fodder, straw or whatever is most convenient. On the back part they should have cornstalk fodder stacked against them, which should be protected from the sheep by a fence run around, if the shelter is not made in a division fence, which will generally be most convenient. The fodder stacked against the back of the pens may be fed away to other stock late in the spring when it will be no longer needed at the pens. The pens that are not open to the sheep (for it will be perceived upon this plan they will have access to only half the pens) may be also covered and will serve to keep pumpkins and cabbage covered with straw for the winter use of the sheep.

It will be perceived that I recommend temporary shelters instead of permanent ones. For which I give the following reasons: My system contemplates a rotation of crops, and this meadow will in a few years be cultivated in other crops ; and another meadow with another set of temporary shelters be brought into requisition. The manure that accumulates about the pens will be easily spread over the meadow, or over the adjoining corn-fields. The straw used for covering the pumpkins and cabbage may be thrown into the pens for a litter as they are fed away. But above all, this plan will prevent the sheep from being crowded in large numbers in one pen, which is sure to injure their health. Clover makes the best hay for sheep, but it re-

---

continue as abundant as they were the last season they will cause the sugar beet to be a very uncertain or laborious crop to raise.

I killed them off mine three times, and each time my beets began again to put out leaves and grow, but they came again in such numbers as to cause me utterly to despair of exterminating them. M.

quires more care in stacking out than other hay. Clover stacks should be topped off with straw or timothy or blue grass hay in the following way. As soon as the stack is built up to the middle, straw or some other hay should be placed all round the outside as you proceed in building, for a foot from the outside, and all the centre filled with clover hay; this should be continued until the last course, which should be entirely of straw or some other hay. A stack built in this way will present on the outside, from the middle up, the appearance of being composed of straw or other hay, and will turn the rains off the stack. Clover hay will permit the rains to run through it, unless thus protected. Clover also suits better in a proper rotation upon a farm than most other grasses, yielding a large crop of hay the year after the ground has been in small grain, and enriching the ground very fast. This subject properly belongs to the treatise upon the best rotation of crops; so for the present I will say no more upon the subject.

As the selection of males is an important matter in the rearing of sheep and the chief instrument whereby the flock is to be improved, I will give the following description of a good ram, taken from Culley's Treatise on Live Stock: "His head should be fine and small; nostrils wide and expanded; eyes prominent and rather bold and daring; ears thin; his collar full from his breast and shoulders, but tapering all the way to where the neck and head join, which should be very fine and graceful, being perfectly free from any coarse leather hanging down;* the shoulders broad and full, which must at the same time join so easy to the collar forward and chine backward, as to leave not the least hollow in either place; the mutton upon his arm or foreleg must come quite to the knee; his legs upright, with a clean fine bone, being equally clear from superfluous skin and coarse hairy wool, from the knee downwards; the breast broad and well forward, which will keep his forelegs at a proper wideness; his girth, or chest, full and deep, and instead of a hollow behind the shoulders, that part by some called the forelock should be quite full; the back and loins broad, flat, and straight, from which the ribs must rise with a fine circular arch; his belly straight; the quarters long and full, with the mutton quite down to the hough, which should neither stand in nor out; his twist (i. e., the junction on the inside the thigh) deep, wide, and full, which, with the broad breast, will keep his forelegs open and upright; the whole body covered with a thin pelt, and that with a fine, bright and soft wool."

Besides the above characteristics, it is of the utmost importance that the wool be of the quality desired. And he should be pure blooded of his kind.

In the mountainous regions, if large flocks should be kept, the shepherd should be almost constantly with the sheep. In enclosed lands a very effectual guard against dogs is two or three cows with young calves, in the same lot with the sheep. If a dog comes into such a pasture, the sheep will run to the cows, and they will be ready to fight for their calves, and will immediately chase the dogs out of the enclosure. I have lost no sheep with dogs when I have kept them with cows and their young calves.

There is at least four millions of acres of mountain lands within the boundary of Kentucky, and it would be a very moderate calculation to say that those mountains would support one sheep to the acre now, and as they become improved, two or more would find support there. Four millions of sheep would require a population to attend to them of forty thousand persons, supposing that every man, woman and child could attend to one hundred each, and would afford an income of one hundred dollars for each member of the family, calculating the wool at one dollar per fleece, beside the increase of the flock.

It would require 30,000 persons to manufacture this wool (if done by hand) into coarse cloth, and a much larger number to make fine cloth.

Thus those mountains would easily be made to sustain four millions of sheep, which would give wages of $100 each to seventy thousand inhabitants.

In Spain and some other countries the wool is washed after the sheep have been shorn. In England, Ireland, Silesia, Saxony, and in the northern parts of the United States the wool is washed upon the sheep, The following is Baron Shultz's account of the Swedish manner:

"Before shearing, the wool is almost universally washed upon the sheep. Some persons wash the sheep in the open sea, or in running water, but this is never so clean as when the sheep are first washed in a large tub, with one part clear lie, two parts lukewarm water, with a small quantity of urine; and then in another tub, with less lie in the water; after which the sheep are washed, laying them always on their backs, with their heads up, in a tub of clean water; and lastly there is poured on the sheep standing on the ground a sufficient quantity of water, which is as much as possible squeezed out of the wool." After the sheep are washed they are driven into a clean green pasture, where they remain until they are dry."

In Silesia the method usually practised simply consists in making the sheep crop a running stream after obliging them to plunge in, from a pretty high bridge.

In Saxony they are made to cross a brook or river; the next morning they are again made to cross the river, in which they are dipped that the fleece may be uniformly penetrated; after which they are stroked or pressed down with the hands, beginning at the head and proceeding thence to their extremities.

After the sheep are dry they are sheared, and the "improved method consists in cutting circularly round the body of the animal, the beauty of which is, in consequence of this, believed to be increased, while the work is more uniformly and closely executed. The shearer holds the sheep under him, either with his knee or left arm, and clips the wool with spring shears, which he can manage with one hand, and thus performs the operation without assistance, unless the sheep are unusually strong and restive. The entire fleece is stripped at once and rolled up together, and the

* The Merino sheep have much loose skin hanging down under their necks and throats. This is a characteristic mark of the breed, yet much may be done to get rid of this leather by selecting those rams that have the least of it.

qualities are afterwards assorted by the wool stapler." Before the shearing is commenced the sheep should have all the coarse and *kempy* wool from the hips, legs, pate and forehead sheared off and kept apart from the other wool. Further, great care should be taken in shearing not to give the wool a second cut, as it materially injures and wastes the wool.

During the whole process of shearing care should be taken that the sheep be not injured by clipping the skin.

The fleece should then be laid on the side that was next the sheep, the sides and belly part turned in, and beginning behind should be carefully rolled to the shoulders, when the wool of the forepart should be rolled back to meet the roll from behind, and should be secured by tying it with twine.

Sheep of the long woolled tribes have been shorn twice in the season, but the experiments have not been attended with any advantage. And short woolled sheep of the Merino breed (which breed does not shed their wool) have been allowed to wear their fleeces several years. Experiments of this kind were made at the French national farm of Rambouillet, from 1804 to 1814, which proved that fleeces worn from three to five years were superior in staple and produced a larger sum than those that were annually shorn. This was also the case in an experiment lately made by Lord Western, whose Merino wether with a fleece of three years' growth produced thirty-two pounds of wool twelve inches long and of beautiful and fine quality.

Lord Western proposed to show a Merino wether against any other breed, on condition that size should not pass for merit; and Mr. Hicks took it up, and produced a Southdown wether supposed to weight 160 lbs., and the judge decided in favor of the Merino.

The butcher (Mr. Barwell, of Witham) who purchased the Merino, says, (in a letter to Lord Western,) "the carcass of this sheep, inside and out, was as good as I ever had; and in point of color the Merinoes carry generally a brighter red and white than any other breed.*

A writer in the western Farmer and Gardener over the signature of "Umbra," who writes like a man of sense and observation, (but whose opinions and observations are not entitled to as much weight as if his name had been given,) says that the cross of the Southdown with the Merino and with the Leicesters have each proved failures.†

A letter from Mr. Twyman, an English gentleman, says, that he has completely succeeded in combining the good qualities of the Southdown and Leicester, the wool being as long as the latter but much finer and closer like the former. One hundred which were shorn at thirteen and a half months old, produced, on an average, nine and a half pounds of wool each. The sheep were sold directly after being sheared at three guineas each, and two shillings per lb. was refused for the wool.

The importation of wool into England in 1827, (the only year that I have the entire amount,) amounted to 29,122,447 lbs. Since that time the amount imported has increased very much.

England, that is not twice as large as Kentucky, produced in the year 1800, 77,964,760 lbs. of wool, and in 1828, 92,280,480 lbs.*

What England has done Kentucky *can do.*

S. D. Martin.

FARMING AT WESTOVER.

By the Editor.

In the latter part of March, in company with two very young farmers, I visited Mr. John A. Selden, of Westover, and passed the greater part of the day in walking over that highly improved and beautifully cultivated farm, and conversing with its proprietor. Such a visit, to any one who has either agricultural taste or pursuits, cannot fail to bring both pleasure and profitable instruction. Something of what we saw, and what was said, principally by Mr. Selden in answer to inquiries, will be here stated.

Notwithstanding its great amount of annual product, Westover is quite a small farm, compared to the lands of most cultivators in eastern Virginia, even in middling circumstances. The original tract gives but four fields of 100 acres each; and the farm proper now is no larger.—There is some back land since purchased, and as yet unimproved, kept for wood and pasture; and also 100 acres of arable land on the river, still more lately bought, and then generally poor, and which is yet but partly improved, and has as yet added but little to the general product of the farm.

* The number of sheep in the United Kingdom of Great Britain in 1828, was 44,100,000. Supposing that each of these sheep produced one dollar's worth of wool, it would be about $75 each for every *white* man, woman and child in Kentucky, giving to every one in cities their shares. There was exported from England in 1828, $29,898,505 worth of the single article of spun and wove woollen goods, besides many articles in which it formed a constituent part; for instance hats to the amount of $159,485.

In 1839, Australia produced 20,128,774 lbs. of wool, where 22 years before there had been produced in that country only 345 lbs. 100 years ago in Ireland there were 1,500,000 persons engaged in manufacturing wool, and their wages amounted annually to about $58,687,000. About 1830 the number of persons engaged in the manufacture of wool in England was 480,000 to 500,000 and their average wages were from $96, to $100 each. The value of the raw material was about $30,000,000, and the manufactured articles $90,000,000. In 1835 there was imported from England into the United States, $13,000,000 worth of woollen goods. If this had been *made at home* it would have given employment to 130,000 persons at wages of $100 each.

About 1770 machinery which enabled (in 1800) one man to do as much work as had been done by three before, was first introduced.

For further information upon sheep, permit me to refer to the society's* treatise upon sheep and Blacklock's treatise written in England in 1838, and just published in the United States in 1841.

* The (English) Society for the Diffusion of Useful Knowledge. S. D. M.

The addition of this 100 acres permitted Mr. Selden to plan the adding a fifth field and crop, to his before well known four-field rotation. But subsequent circumstances required him to abandon or postpone the intention of that change, before it was commenced; and now, as before, his rotation is the four-field, of three grain crops and one of clover, which has become so celebrated by its successful practice at Curles' Neck, Shirley, and Westover, and which has been so ably advocated by the published opinions and arguments, as well as the successful practice, of Mr. Hill Carter and Mr. Selden. The latter seems to have returned from his meditated partial abandonment, to his "old love" of the four-shift rotation, with even increased ardor and confidence. And though I have heretofore objected to this rotation, as too scourging, and as contrary to the sound principles of rotation (in the three consecutive grain crops,) and though still holding to these opinions, as to lands in general; still it must be admitted, if the question is to be judged of by practical results, that it is scarcely possible to imagine a better rotation for combining profit and improvement, than Mr. Selden's, on his good land, and with his good management. The rotation (as has often been stated in this publication) is 1st, wheat on clover fallow; 2d, corn; 3d, wheat (and oats,) with clover sown, and 4th clover, to be turned in by a deep and well executed ploughing in August and September, then to recommence the course with wheat again. The designed alteration was to introduce a green manure crop of broad-cast field (or Indian) peas the year after corn, to be turned in for wheat; making the rotation, 1st, wheat, 2d corn, 3d, peas, 4th, wheat, and 5th, clover. And this, on lighter or fouler lands than Westover, I still deem a much preferable rotation.

At this season of the year, of course, there is nothing to be seen of crops, except young wheat and young clover. The oats were just being sown, and the land for corn not yet harrowed for planting, but remaining as left by the deep and excellent ploughing done early in the winter. But even at this early season, the fields of both clover and wheat were beautiful. The wheat following corn, (which was on the richest field,) promised better than any I had before seen in that always objectionable succession; indeed, if judged by the growth only, I should have supposed it to be fallow wheat. That however on clover lay, was of course much better.

There are five kinds of wheat growing, and it was remarkable to see such different manner of growth of different kinds, exhibited so early. One object of having so many kinds was to compare their characters and products; and as it is hoped that the results will be noted and reported hereafter by Mr. Selden himself, no more will be here said of the difference of present appearance, or of what he supposes of their qualities. The bulk of the crop is of the Turkey wheat, a kind which he began to raise from a very small stock, 19 or 20 years ago, and which he has continued to prefer, and sow, ever since. He uses great care in fanning his seed wheat, to get rid of all the lighter and smaller grains. This he deems essential to the preserving of a good stock; but with this care used, he does not believe in any wheat degenerating by being continually sown on the same farm. In this, he and his neighbor, Mr. Hill Carter, hold opposite opinions, as stated in a recent communication by the latter to the Farmers' Register.

The clover field was completely covered with green, and nothing but clover to be seen. The remarkable cleanness of the land, and the entire possession that each desired crop has of all the ground given to it, is one of the most striking benefits of his rotation.

Mr. Selden however thinks that one cleansing, or tilled crop, in each rotation, is essential to preserve cleanness, and to obtain a well set crop of clover; though the rotation with clover fallow is more cleansing than without it, even though the one hoed cross (corn) should recur as often, or oftener, as in the three-shift rotation. In proof of the latter opinion, he adduced the fact that wire-grass, which was very troublesome on some parts of his fields, when he commenced his rotation, has been very much diminished, and almost subdued by the present rotation, without any other special care or labor directed to eradicate that pest. He showed me a striking proof of the truth of the opinion, that it is essential to the having of a well-set and clean clover field, that it should be preceded by the hoed or cleansing crop as recently as in his present rotation. In his field which is elsewhere thickly covered by clover, there is scarcely any to be seen on a part bounded by an exact line. The only difference of treatment was, that this part, by some previous difference of cultivation, or change of arrangement of the fields, had remained at rest the year after wheat, instead of being in corn with the balance of the field. During that year of rest it was pretty well covered by a growth of volunteer clover (none being sown on the wheat preceding corn,) and was fallowed and put in wheat with the corn-land of the balance of the field. All alike was sown in clover on the wheat the next February, (1841;) and the result is, that while all the balance of the field of wheat after corn, is completely set in clover, this part has scarcely any clover standing.

Mr. Selden thinks that the best time to sow clover seed is as strictly limited in duration, as the best time to sow wheat; and that that time is generally the last week in February. If sown much earlier, and a warm spell occurs, the seed is apt to sprout, and the plants be killed by succeeding severe cold. If sown much later, and the season be not very favorable, much of the seed may not sprout at all, in time, or the growth be in danger from the summer's drought. But of course it is not possible to come always within this best and short time, and never when sowing after oats—which was going on then—the oat seeding not being finished (March 25th,) and which (contrary to general opinion,) Mr. Selden thought not at all too late for the best prospect of that crop. The clover seed was easily and accurately sown from a seed-box, the advantage of which plan is so great and manifest, that it is strange that any farmer who sees the process can fail to follow the example. The beds being 11 feet wide, the box is made 10 feet long to suit, and is about 4 inches deep, and 3 in width; it is open at top like a trough, and is divided into 10 equal compartments, by cross partitions. In the bottom at every distance of 6 inches, there is bored a hole, (say half an inch in diameter,) each of which is covered by a card or piece of paste-board, through which is *burnt*, by a heated wire, a hole about the

eighth of an inch in diameter. The size of the holes of course must be fixed at first by trial of the rate of seeding. But when once fixed, and the same borer kept for use, there is no more trouble in regulating the rate. The seeding is very regular, and equal. A gallon to the acre is the most that is ever given—and sometimes only 3 quarts, and found an ample allowance. The manner of using this box is for the sower to carry it horizontally across and in front of the middle of his body, supported by a leather strap over his shoulders, and the box kept evenly poised by his hands. He walks at ordinary rate along the middle of each bed, and at every step shifts the box a few inches, first to one side and then to the other. The box is made of light plank only a quarter of an inch thick; and, with seed in every compartment, the weight is not considerable, and the labor light enough. As no skill is requisite, any laborer, at first trial, can sow with perfect accuracy. I had deemed my plan of sowing, by throwing the seeds against a board, (described in a former volume,) to be a very valuable improvement upon the usual mode of casting the seed. But the sowing box is better. And this is an example of how long a simple implement or process may remain almost in disuse, merely because it is not seen in actual operation. This sowing box is pictured and described in Bordley's Husbandry, where I saw it more than thirty years ago, (for it was one of the books read for amusement in my boyhood,) and which I have never since heard of being used, until seen now. There is another machine described in that same book, for gathering clover seed, by a comb-edged box on wheels, or barrow, drawn by a horse. I went once to the shop of Jabez Parker to order such a machine to be made, but was discouraged and prevented by learning that he had made but for one order, and that one a long time before.—Hence, I concluded, as of the sowing box, and as most farmers are very apt to conclude of new implements known only by description, that it would certainly have been more in use, if not attended by some insuperable objection. On the other hand, the most *taking* recommendation of any new implement, is that many other farmers have already bought it. Thus, hundreds, (including myself with many much better farmers, whose *names* alone seduced me into the scrape,) formerly bought Clark's thrashing machine, the most unmitigated cheat of a machine of which I ever heard; as to no purchaser was it worth a cent. If agricultural societies were worth any thing, one of their most useful operations would be to cause to be *tried* as well as *exhibited*, all new or improved implements, by having the trial executed by a judicious farmer, and causing to be published his report of the result. Such *practical* and *disinterested trials* of implements would bring into use all that deserve it; whereas, the mere *exhibition* of new implements and machines at the show of an agricultural society, is rather calculated to aid the success and progress of humbug and deception.

There was one practice seen, and which seemed by the results to justify Mr. Selden's approbation, which I would otherwise have thought certainly wrong, and have always acted and advised otherwise. This is, the *not* cleaning out the water-furrows between the beds, but on the contrary rather working so in preparing for and covering the seed wheat, as partially to fill up and level the existing furrows. I had always supposed that any land requiring beds and water-furrows, for better drainage, would require that the furrows should be kept open and clean. And also, supposing that any plants growing therein would perish with wet, or at least be feeble and produce poorly, it was inferred that it was even better for economy to have a deep, narrow water-furrow, open and clear of all plants, that the shoulders of the furrows, or outsides of the beds, might be better raised, and safer from wetness. Mr. Selden however, thinks differently, and says that both the wheat and clover grow as well, generally, in the furrows as on the beds, excepting from the greater depth of soil and greater fertility of the crowns of the ridges. Even this difference does not prevent the heads of wheat, when grown, appearing nearly level. On spots particularly subject to wet, only, he has the water-furrows kept deep and open. It is certain that at the time of viewing, the wheat in the furrows where not opened seemed none the worse for being so low. It may yet be questioned whether land whose texture and surface will permit such treatment, though a clay loam, and nearly level, as is this farm, might not be cultivated level, or without beds, safely, and yield as well. Mr. Selden thinks that even if this were so, it is more economical of labor in ploughing to have beds. One of the gains which he counts upon, is the space left unbroken and covered by the meeting on the old water-furrow of the two first furrow-slices thrown, in reversing the beds, when turning in the clover lay for the next crop of wheat. The space so covered by the large ploughs used, must be at least two feet in the bed of eleven feet. However contrary to reason, as some might suppose, Mr. Selden, and most other good farmers hold with "Arator" that there is no disadvantage in leaving this covered strip unbroken. The so leaving it, certainly makes much neater and easier ploughing, and in a greater degree than the mere saving the labor of ploughing two more furrows.

Upon inquiring of Mr. Selden what were his views as to applying manure on the surface, he said that he carried out manure, and so applied it without the fear of loss, at any time of the year, when he had it to dispose of, and the labor was convenient. He preferred, however, to plough under the unrotted farm-yard manure that was to be used for the corn crop. He was then hauling out wheat straw from the stack, and spreading it on the clover field at the rate of about 18 or 20 large ox-cart-loads to the acre. This quantity, when spread, was so thick that I should have feared it would smother much of the clover; but was told there was no danger of that result. But though this top-dressing will be no doubt highly beneficial to the clover and still more to the wheat of next year, I think it would have been far better if applied last summer or autumn, or early in winter. However, it could not be earlier here, as the carts have been hauling out the straw (of a crop of 5000 bushels of wheat made last year,) as long and as often as the limited force, and the other heavy demands for labor permitted. One of the younger farmers present, who would not presume to compare either farming knowledge or practical operations in any respect with Mr. Selden,

had used straw to considerable extent in like manner, but much earlier, and therefore as he deemed more profitably. This was last summer, and only on the galled and poorer spots of his reaped wheat field, sown in clover the preceding spring. The clover on such places already is better grown than on the immediately surrounding and better ground. As much as convenient of this straw was carried out to the field as thrown out from the thrashing machine, in return loads of the carts bringing in wheat from the field. This saved nearly all the cost of carriage; and the carts were loaded (carelessly and but partially) with less labor than would have been required to put the same straw on the stack. Besides, if the loaders in the field had any spare time between the departure of one cart and the arrival of another, they could be profitably employed in spreading the return loads of straw.

To this *late* application of straw, by Mr. Selden, which could not be helped, I must add one other fault in his management which he might and ought to have avoided, as he has been throughout a regular reader of the Farmers' Register, where he might find more correct views on this head. Having recently bought a vessel load of slacked but still caustic stone lime, he had 500 bushels of it spread over the litter in his cattle yard. The action of the quick-lime on the dung and other most putrescent parts of the manure will necessarily be injurious, and more or less destructive of the enriching principles.

Mr. Selden uses lime largely, and to great benefit. He applies it in the manner described in vol. i., as then practised by the late Fielding Lewis of Weyanoke, about 72 bushels to the acre. Oyster shells cost 62 1-2 cents the hogshead of 18 bushels. Latterly, slacked stone lime is brought by vessels from New England, loaded in bulk, which may be bought for 10 or 11 cents on contract. It has been sold here as low as 9 cents. It is cheaper, Mr. Selden thinks, than using water-borne marl; which is gratifying to learn, as all farms on tide-water may be as cheaply supplied with lime, whereas but few (requiring it) can obtain marl by water carriage. Mr. Selden never fails to find satisfactory benefit from his liming. He has not yet quite dressed all his arable land. As soon as gone over once, he intends to begin a second application in smaller quantities.

Gypsum is sown regularly on every clover crop, and generally, though not always, with good effect. From failing formerly, Mr. Selden was induced to believe that it was less effective if sown before the severe frosts were over; and therefore always delays the application until after that danger is passed. In this opinion, he must be mistaken.

Though clover is greatly improved by the liming, yet it stood well on all the farm even before lime was applied. That, and the effectiveness of gypsum also in advance of the liming, would alone suffice to prove to me that the soil was originally rich, "neutral," and of admirable constitution, even if its appearance and texture did not teach the same.

Mr. Selden is of opinion that the growth of oats is more exhausting than wheat; but deems the crop essential to farm economy, in the greater cheapness of feeding horses by using part oats, with the straw, instead of with all corn and corn fodder. His regular mode and measure of feeding his work mules are as follows for each one: morning, two quarts of corn alone; noon, one quart of corn and half a bushel of cut oats; night, one quart of corn and a bushel of cut oats. On this allowance, if it be certainly and regularly given, Mr. S. considers that mules cannot fail to keep in good order, while doing good work. It is very certain that the ploughing teams of Mr. S. are kept in good order; and all who know the rotation and manner of tillage at Westover, know that unusually heavy ploughing labors are performed. No corn fodder gathered, or hay made or used. For the usual business of pulling of corn fodder there is no time or labor to spare; and none is pulled, except a little for the sheep; and the clover is given as manure to the land it grows on, instead of being mown for hay. Thirty acres of the richest part of the land in corn the preceding year are annually put in oats, and the crop is an ample supply for the 12 working mules and 3 horses kept on the estate. As the oats grow on the richest land, of course there is so much the more of straw in proportion to the grain, and the chopped stuff is much poorer than is usual of oats from poor land.

Most persons may find advantage in comparing practically and accurately, the above mode of feeding with their own, or that which is usual where plentiful or sufficient feeding is *intended* to be allowed. This allowance is, for each mule or horse, from 6 to 10 *ears* of corn, (selected at the discretion of the ploughman, who of course picks the largest size,) thrice a day, and as much corn fodder in the rack as the animal will eat, and more for his waste.

The readers of the Farmers' Register may remember that Mr. Selden, in his first communication, vol. i., lamented his not being able to make more use of oxen, owing to the fact of his cattle being so subject to die of distemper. Upon inquiring concerning that matter, I learned that there had been no case of that strange disease on his farm for some years. He attributes his exemption, (and thinks that the same means of prevention will serve every where,) to the use of a mixture of salt, sulphur and tar, kept constantly in troughs for the cattle to lick at will, through summer and autumn. I have heard from another experienced and observant farmer, the assertion of the like confidence in that preventive medicine. This distemper is a most mysterious disease; and it is much to be regretted that so few of the remarkable facts of its prevalence and disappearance have been made public. During the time that its frequent occurrence at Westover was a serious obstacle to the full use of oxen, and since to this time, on the Coggins' Point farm, immediately across the river from Westover, there has not been a known case of that disease in 29 years. Nor have I known of a certain case in the neighboring part of Prince George county during that time; though such may possibly have occurred, and even on my own farm formerly, without the true character of the disease being suspected. Indeed, while the distemper has been most destructive elsewhere, it is not understood to have existed in that neighborhood since about 1780, when, in the course of two summers, more than half the cattle of the county, and especially the fattest, died of distemper. This I have

heard from William Weeks, an intelligent observer, and now the oldest man living in that neighborhood.

Mr. Selden's oxen now (raised on the farm) are much finer animals than are often met with in eastern Virginia. He sold two pairs not long since to be worked at the Navy Yard, Portsmouth, for $100 the pair, which is about double the usual price of what are called *very good* oxen. Those we saw at work would prove that his cattle fare well, and likewise that the cause of the distemper is not (as some suppose) to be found in clover, or other good grass, being plentiful, and the cattle being fat.

The Hessian fly, so destructive to wheat elsewhere and generally, is not found to be any important cause of diminution to the crops at Westover. If sown in good time, (say commencing the 10th of October,) and the land is good and well prepared, the vigor of the growth will be sufficient protection against the attacks of the fly. Mr. Selden does not doubt but that these insects are numerous in his wheat, and does not suppose that their depredations are harmless. But at least they show such little effect, as never alone to have prevented the making a good crop from good land, other circumstances being not unfavorable.

In my own practice, I have found no such exemption from this infliction. But my land was not only much less fit to bear heavy crops of wheat, and my cultivation far less perfect than here, but also, the wheat fields were not grazed and gleaned after harvest by stock, and therefore all the wasted grains grew to furnish food for an intermediate brood of Hessian fly. And if there are successive broods of the fly, this must be a very efficient means to nourish and increase them. I am now convinced of my error in adhering so entirely and so long to the non-grazing system. Besides the benefits that I would count on to the stock from gleaning the wheat fields after harvest, and the preventing the growth of volunteer wheat to sustain a new brood of Hessian fly, Mr. Selden thinks that the partial grazing of the field, or rather the trampling which accompanies it, is essential to the best success of the clover sown on the wheat. And if the grazing after harvest is beneficial, for this reason, on the stiff loam of Westover, it must be much more necessary and desirable on soil too light to be well adapted to wheat.

OIL AND STEARINE FROM LARD, &c.

Published by the National Agricultural Society.

[The following communication on the subject of oil and stearine, has, on request, been transmitted to the Commissioner of Patents, and will be read with interest.]

Stearic acid, or stearine, as it is improperly called, is the solid constituent of fatty substances, such as oil, tallow, lard, &c., and which can be separated in a crystalline form by saponification with alkaline matter and abstraction of the alkali by an acid. By this process fats are convertible into the stearic, margaric, and oleic acids combined, to separate which alcohol is used, which holds the two latter in solution after having dropped the stearic acid in crystals.

Pure stearic acid is prepared thus: boil together in the proper equivalent proportions a solution of an alkali, say potash with tallow; by this process a soap is formed; of this soap dissolve one part in six parts of hot water, then add to the solution 40 or 50 parts of cold water, and set the whole where the temperature is about 52° Fahrenheit. The bistearate and bi-margarate of potash, pearly in appearance, fall to the bottom, which are to be separated by and washed upon a filter. An additional quantity of these salts is afforded by evaporating the filtered liquor, saturating with an acid the alkali left free by the precipitation of the above salts, and then adding water. By a repetition of this operation, if conducted carefully, the solution is freed from all of these solid acids, leaving therefore nothing but the oleic. After having washed these bi-salts, digest them in twenty-four times their weight of boiling alcohol of specific gravity 0.820, upon cooling the bistearate precipitates, while the greater part of the bi-margarate and the remainder of the oleate is held in solution. By redissolving in alcohol as before, the whole of the bi-margarate is got rid of, leaving the bi-stearate alone, the purity of which can be tested by decomposing a small portion in water at the boiling temperature with hydrochloric acid, letting it cool, washing the stearic acid obtained, and exposing it to a heat, which, if pure, will not melt in water under 158° Fahrenheit; should it fuse at a lower temperature, it is to be inferred that there is more or less margaric acid present, to get rid of which repeat the solution in alcohol in the mode as directed before.

We then have *pure* bi-stearate potash. From this we separate the stearic acid, by decomposing it in boiling water with hydrochloric acid. The stearic acid which falls down, is to be washed by melting in water, cooled, dried and dissolved in boiling alcohol, from which crystals will fall during refrigeration.

Thus obtained, the stearine contains combined water, from which it is difficult to separate it.

In June, 1825, a patent was granted in England to Mr. Gay Lussac for making these candles, but owing to their comparatively great cost, they could not, although superior to other kinds, be introduced into general use. Lately, however, the great objection has been obviated by the many improvements which have been made in the *modus operandi* of manufacturing these candles. The substitution of lime for potash in saponifying, is one of the most important; and to such perfection has the process now been brought, that the London block, containing only 3 per cent. of wax, and from which these candles are made, bears so handsome an appearance, and is of so good a quality, as to render it difficult to distinguish it from the most refined product of the bee.

The following is the process by which these candles are made on a large scale, both in England and France:

Tallow, lard, or any fat, is boiled with quicklime and water in a large vat, by means of perforated steam pipes distributed over its bottom. After several hours' active boiling, the combination becomes sufficiently complete. The stearate thus formed is allowed to cool until it becomes a concrete mass; it is then to be dug out, transferred to a suitable vessel, and decomposed by a sufficient quantity of sulphuric acid. This de-

composition of the soap, says the patentee, should be made in a large quantity of water, kept well stirred during the operation, and warmed by steam introduced in any convenient way. When the mixture has stood sufficiently long, the acid of the fat or tallow will rise to the surface, and the water being drawn off, will carry the alkaline or saline matters with it, but if the acids or tallow should retain any portion of the salts, repeated portions of fresh water must be added to it, and the whole well agitated until the acids have become entirely freed from alkaline matter.

The washed mixture of the three acids, stearic, margaric, and oleic, is next drawn off into tin or other suitable pans, and allowed to cool, and then reduced to thin shreds by a tallow cutter—an instrument used by all tallow chandlers.

The next step is to encase the crushed mass in canvass or carga bags, and then submit it to the action of a powerful hydraulic or the stearic cold process, a machine made for the purpose. By this means a large quantity of the oleic acid is expelled, carrying with it some little of the margaric. The cakes, after considerable pressure, are then taken out, and again subjected to the action of steam and water; after which the supernatant stearic acid is run off into pans and cooled. The cakes are then reduced to a coarse mealy powder by a rotary rasping machine, put into strong canvass bags, and submitted to the joint action of steam and pressure in a hydraulic press of appropriate construction, called Maudelay's stearine cold press. By these means the stearic acid is entirely freed from oleic acid. It is then subjected to a final cleansing in a tub with steam, melted and cooled in clean vessels. These cooled masses, owing to their crystalline texture, are unfit to be made into candles, it is therefore necessary to crush them into powder, and fuse along with it in a plated copper pan a sufficient quantity of arsenious acid. The stearine is now ready to be moulded into candles.

The wick to be used in the manufacture of these improved candles is to be made of cotton yarn, twisted rather hard, and laid in the same manner as wire is sometimes coiled round the bass strings of musical instruments. For this purpose straight rods or wires are to be procured, of suitable lengths and diameters, according to the intended size of the candle about to be made; and these wires having been covered with cotton, coiled around them as described, are to be inserted in the candle moulds as the common wicks are; and when the candle is made, and perfectly hard, the wire is to be withdrawn, leaving a hollow cylindrical aperture entirely through the middle of the candle.

C. MORFIT.

Philadelphia, February 16, 1842.

—

Mode of manufacturing Elaine and Stearine from Lard, &c. : Patented by John H. Smith, 122 *Front Smith street, New York city.*

To all whom it may concern : Be it known that I, John H. Smith, of the city of Brooklyn, in the county of Kings, and state of New York, have invented a new and useful improvement in the manner of separating from each other the elaine and stearine which are contained in lard, by means of which improved process the operation is much facilitated, and the products are obtained in a high degree of purity ; and I do hereby declare that the following is a full and exact description thereof:

The first process to be performed upon the lard is that of boiling, which may be effected either by the direct application of fire to the kettle, or by means of steam ; when the latter is employed, I cause a steam tube to descend from a steam boiler into the vessel containing the lard ; this tube may descend to the bottom of the vessel, and be coiled round on the said bottom so as to present a large heating surface to the lard, provision being made for carrying off the water and waste steam in a manner well known ; but I usually perforate this tube with numerous small holes along the whole of that portion of it which is submersed below the lard, thus allowing the whole of the steam to pass into and through the lard. To operate with advantage, the vessel in which the boiling is effected should be of considerable capacity, holding say from ten to a hundred barrels. The length of time required for boiling will vary much, according to the quality of the lard ; that which is fresh may not require to be boiled for more than four or five hours, whilst that which has been long kept may require twelve hours. It is of great importance to the perfecting of the separation of the stearine and elaine, that the boiling should be continued for a considerable period as above indicated.

My most important improvement in the within described process, consists in the employment of alcohol, which I mixed with the lard in the kettle, or boiler, at the commencement of the operation. When the lard has become sufficiently fluid, I gradually pour and stir into it about one gallon of alcohol to every eighty gallons of lard, taking care to incorporate the two as intimately as possible ; and this has the effect of causing a very perfect separation of the stearine and elaine from each other by the spontaneous granulation of the former, which takes place when the boiled lard is allowed to cool in a state of rest. I sometimes combine camphor with the alcohol, dissolving about one fourth of a pound in each gallon of alcohol, which not only gives an agreeable odor to the products, but appears to co-operate with the alcohol to effect the object in view ; the camphor, however, is not an essential ingredient, and may be omitted. Spirit of lower proof than alcohol may be used, but not with equal benefit.

After the boiling of the lard with the alcohol has been continued for a sufficient length of time, the fire is withdrawn, or the supply of steam cut off, and the mass is allowed to cool sufficiently to admit of its being laded, or drawn off into hogsheads, or other suitable coolers, where it is to be left at perfect rest until it has cooled down, and acquired the ordinary temperature of the atmosphere ; as the cooling proceeds, the granulation consequent upon the separation of the stearine and elaine will take place and become perfect. The material is then to be put into bags, and pressed moderately, under a press of any suitable kind, which will cause the elaine to flow out in a state of great purity, there not being contained within it any appreciable portion of the stearine; this pressure is to be continued until the stearine is as dry as it can be made in this way.

The masses of the solid material thus obtain-

ed are to be remelted, and in this state to be poured into boxes or pans, of a capacity of ten or twelve gallons, and allowed to form lumps which I denominate blocks; then when removed from the vessels and piled, or stacked up for a week or ten days, more or less, the room containing it should be at a temperature of nearly 80°, which will cause a sweating or oozing from the blocks, and they will improve in quality; the blocks are then to be rolled into cloths or put into bags, and these placed between plates, and submitted to very heavy pressure by means of a hydraulic press. After this pressure it is brought again into the form of blocks, and these are to be cut up by means of revolving, or other knives, or cutters; the pieces thus obtained are to be put into bags, and subjected to the action of hot water, or of steam, in a press, until it becomes hard enough to be manufactured into candles, or put up for other purposes to which it may be desired to apply it.

The manner of subjecting it to the action of heated water, or of steam, is to place the bags containing the stearine in a box, or chest, into which heated water, or steam, may be introduced, but not to such extent as to fuse the stearine. A follower is then to be placed against the bags contained in the box, or chest, and moderate pressure made upon them; the material will now be found to have acquired all the required hardness, and to posses a wax-like consistence, such as would generally cause it to be mistaken for wax.

I am aware that alcohol has been used for the purpose of separating elaine and stearine from each other in analytical chemistry, but the lard or other fatty matter consisting of these substances, has, in this case, been dissolved in the heated alcohol, and the whole has been suffered to cool together; this process would be altogether inapplicable to manufacturing purposes, as the cost would exceed the value of the product. In my manufacturing process, instead of dissolving the lard in alcohol, I add a small proportionate quantity of the latter to the former, the whole of which is driven off at an early period of the ebullition, but by its presence, or catalytically, disposes the elaine or stearine to separate from each other, which they do after long boiling and subsequent cooling. I do not, therefore, claim the use of alcohol in separating elaine and stearine from each other, by dissolving the fatty matter in heated alcohol, and by subsequently cooling the solution; but what I do claim as of my invention, and wish to secure by letters patent, is the within described method of effectively promoting their separation, by incorporating alcohol, highly rectified spirits, with the lard in small proportionate quantities, say one gallon, more or less, of said alcohol, or spirit, to eighty gallons of lard, and then boiling the mixture for several hours, by which boiling the whole of the alcohol will be driven off, but will have left the elaine and stearine with a disposition to separate from each other on subsequent cooling, as herein indicated and made known.

JOHN H. SMITH.

ON THE DIFFERENT SCHEMES OF ROTATION.

To the Editor of the Farmers' Register.

In your February number there is a very interesting paper, over the signature of N., on the subject of rotations. Being myself an ardent votary to the cause of agriculture, and having had some little experience on the subject of rotations, and being still in quest of truth, or rather light, upon the subject, I am induced to comply with the request of my brother farmer, in my poor way, as far as my limited experience and observation extends, upon the subject of his inquiry.

Looking to experience as the only correct teacher in agriculture, and having had so few successful pioneers in this art, in this our much abused and maltreated tide-water section of Virginia, that it has become, or was necessary until recently, (as we have now many more good farmers in the field than formerly,) for every one that wished to improve his lands, or his husbandry, to experiment for himself; it has therefore fallen to my lot to have tried most of the rotations of the different gentlemen as brought in review by N. That most or all the gentlemen mentioned by N. are successful cultivators, and improvers of the soil, I do not doubt, and that all have done well under the rotation followed by each; but it does not follow that some, if indeed not all, might not have done better under another rotation, and I hardly suppose that either gentleman would contend that his was a perfect system. Let us then first examine a little into the three field rotation, as recommended by Tabb, Roy, and Harrison; as, if my memory does not deceive me, that was the rotation recommended by those gentlemen. Mr. Tabb, then, in the first place, owns one of the finest estates in all Virginia, or perhaps naturally in America; when I say naturally, I mean original fertility of soil, and one that perhaps, with almost any tillage, it was impossible to wear out, being of the very best description of Gloucester low grounds; a soil perhaps of several feet in thickness, unless sooner coming in contact with marl or some calcareous earth, which is the underlying stratum of this soil. Superadded to this, Mr. T. is a very judicious man in all his affairs, and a most excellent cultivator and improver of the soil; and also having it in his power, if necessary, to draw from extraneous funds to aid in his farming operations. And, if I mistake not, Mr. Tabb has a fourth of his farm in a standing pasture, which enables him to keep a very large stock, by which means he is enabled to apply a very large amount of animal and animalized matter to his land, independent of the clover and other vegetable matter grown on the fields cultivated. Is it to be wondered at that, under all these peculiar advantages, Mr. Tabb's land should do well and even produce abundant crops under the three-field rotation? Advantages that scarcely any lands in the state are subject to, to wit: being naturally rich, producing perhaps, when cleared, 10, 12, or more barrels of corn to the acre, a soil almost inexhaustible; for many years under the excellent management of its owner, with every adventitious circumstance that could be desired; I say it is not to be wondered at that it should do well under the three-field rotation of corn, wheat and clover. But if I mistake not, there is some fallowing in the way too, with Mr. Tabb, so that I

think a part of his land does not come under a hoe crop but once in six years. Now surely it could not be advisable to put an old worn out estate of naturally poor land under the same system as Mr. Tabb's, if we desire or expect a rapid, or indeed improvement at all.

Let us now take a view of Mr. Roy's estate, with his three-field rotation. Mr. Roy's estate lies in Mathews, the adjoining county to Gloucester; his land, not originally of the naturally fertile soil of the Gloucester low grounds, but still I believe it was what we call good land, of character to retain all that is put on it in the way of improvement. I do not know that he has used marl or lime; if he has not used the latter, it must be because he does not think his land requires it, as he could I suppose easily command it in any quantity and at a cheap rate. But this I know, that he, his manager, and his father before him, have been good manurers, and if I mistake not, he manures the greater part of his field intended for corn every year that it comes into cultivation; so that I should not think it at all strange that his land should improve under the three-field rotation. But it must be kept in mind that, situated as Mr. Roy is, immediately on an inlet of the Chesapeake bay, he has access to as much sea weed as he can use, and perhaps other resources for making manure, that are not available to every one, and no one ever doubted that if you could manure your land every year, it would improve under an annual tillage. Whether the Mathews lands succeed well in fallow for small grain I am not advised; if they do not, doubtless the three-field rotation may be the most profitable they can adopt. But even that I should doubt; as a longer action of the atmospherical influences upon the same surface, together with the increased quantity of stock and manure, which a more lengthened rotation would admit of being kept and made, would, I have no doubt, with less labor, produce a greater amount of crop.

We will now visit Brandon, and see if Mr. Harrison enjoys no facilities for improving his land, other than are common to farmers generally. There can be no doubt but that the land on the Brandon estate must have greatly improved under the occupancy of the present owners, as I have been credibly informed that the product is now double of what it was under the regime of the father of the present occupant. But I am rather under the impression that some of the Brandon land is under the four-field rotation, and that they fallow on at least a portion of the estate. But be that as it may, I have always heard that the land on that estate was originally good, if not rich; it is also, I believe, a fine wheat soil, and well adapted to clover, and I presume the plaster acts well. I believe now the lands of those estates are all limed or marled; how much they had improved before they commenced liming, I am not aware. Another advantage I think I have heard those estates enjoyed was, that of an extensive marsh or piece of wet land, too wet for cultivation, but affording good pasture to a large number of cattle, thereby indirectly adding another field to the rotation, grazing the cultivated fields only at certain periods of the year, giving the arable lands the benefit of all the manure they make both winter and summer; and I presume grazing is allowed partially at particular seasons. I do not, therefore, Mr. Editor, think that either of the farmers alluded to by N., pursuing the three-field rotation, ought, properly speaking, to be held up as models for a general system. Nor do I think it by any means proved that either of these gentlemen, under a more lengthened rotation, with their general good management, would not have arrived at much higher results than they have yet attained. They have no doubt thought it best to "let *well* alone," and in their situations doubtless they were right. But "as one swallow does not make a summer," neither do three good farmers, being comparatively successful under peculiar circumstances in a particular rotation, make that rotation preferable to all others.

As your correspondent N. seems to have passed over the four field-rotation, it might not be necessary that I should notice it in this communication; but as we are writing and speaking for information upon the subject of rotations, I will even give it a word in passing. The Arator four-field system I have seen tried in all its varieties, and have never seen much good corn from it in any way. It is true Arator himself succeeded very well with it at Hazlewood; but no where else that I am aware of. That is, he succeeded very well in bringing back his land to its original fertility, and he made very heavy crops of corn; but never made wheat successfully, as I have been informed. But be it remembered, that Hazelwood was originally of the best description of Rappahannock low grounds. The four-field rotation as pursued on James river of late years by those successful and justly celebrated farmers, Messrs. Carter, Selden, Harrison, &c. &c., on originally good land, of deep soil, with the management of these gentlemen succeeded very well for a time, but the two former have abandoned it, thinking the five-field a better, or even six-field preferable, when circumstances allowed it. This I inferred from their communications a year or two ago in the Register. But there is a four-field rotation which a friend of mine is now trying, which, if he succeeds with making clover take well after corn, will, I think, supersede all others on natural corn land, that is, on land naturally better adapted to corn than wheat, particularly all those extensive flats lying on our tide-water rivers, where corn is the main staple, and navigation at the doors. The rotation then, which my friend is now proposing to try, is simply reversing the Arator four-field system; that is, by following wheat with corn instead of corn with wheat, say thus, 1st wheat, 2nd corn, (sowing clover seed the last time the corn is cultivated,) so that the third year the clover will be at maturity; that year let it ripen and fall on the land, and the fourth year pasture it, and that fall fallow it and sow it in wheat, reserving as much for oats the next spring as the farmer may deem advisable. By this system, if the clover succeeds after corn, you will have the full benefit of the clover crop by protecting the lands from the summer suns as well as the winter frosts, and washing after corn. And the next year the stock (as much by the way as the land will *well* maintain) trampling and breaking the dry vegetable matter to pieces, and depositing their manure and urine upon it, your land will have a fine top or surface dressing of vegetable and animalized manure. The latter I hold to be altogether indispensable to the attainment of a high

state of productive fertility. I say *productive* fertility, because I have seen a great deal of land that was seemingly rich, but would not produce heavy crops of grain, and I believe for the very reason that it wanted the animalized matter and the compactness which the hoof gives it. It being now admitted, I believe, by most judicious farmers that applying manure on the surface and on grass land is the preferable way of using it, my friend proposes applying all his winter-made manure to the clover field the spring after it is sown. The summer cow-pens would of course be on the pasture fields intended for fallow that fall, which being cleansed of a number of pests by grazing and of all over-luxuriant vegetation, with a handsome sprinkling of manure all over the field, and the land, if light, rendered compact, and if stiff, the sponginess removed by trampling, will by September be in a fine state for the plough, and, I should think, of productiveness for the wheat crop. We all know that corn will grow well after wheat, but it is very rarely that wheat ever succeeds after corn. And the reason is very manifest; because in the cultivation of the corn crop, all the productive powers of the land are brought into action, and the wheat following immediately after, before the land has any time to rest from the draught of the most exhausting crop we grow, the natural result must be an indifferent crop of wheat. Whereas, by following wheat with corn, the wheat does not exhaust the land as much as corn, and we have the whole of the aftermath of stubble, clover, grass, weeds, &c., to turn in, as well as giving the land eight months to recuperate its soil on or near the surface. None of these advantages are derived by the wheat after corn. I am aware it is considered bad husbandry in all the good farming districts in Europe to follow one grain crop with another, and I dare say it is; but still I have generally seen corn succeed very well after wheat, particularly on good land. It strikes me this proposed rotation of my friend has but one objection to it, and that may be a fatal one, viz.: the doubt of the success of the clover, after corn. But he is sanguine of success on good land that has been marled. But, as I before observed, I would not advocate this system to the exclusion of the five or six-field rotation on other than lands naturally much better adapted to corn than wheat, and that to be on navigable water, or very contiguous to market.

Having dwelt much longer on this part of the subject than I had intended, we will now pass on to the five-field rotation, which is more particularly the subject of inquiry of your correspondent N., and the only one I intended at first to touch upon in this communication. N. says he has "unconditionally made up his mind to adopt the five-field rotation," and therefore, if I had the disposition, it would be useless to attempt to divert him from it; but in this I have no wish; as from some years' experience I can highly recommend it, as at least a profitable and improving rotation. I will not say it is preferable to any other, or to the six-field rotation; but I know that in a few years a farm may be made to double its production. But to proceed more directly to answer his queries respecting the choice of the two methods pursued by himself, and that of Mr. Wickham, or the common five-field rotation as pursued by most persons who have adopted that number of fields, I unhesitatingly answer, after some experience with both, that I prefer the latter, or Mr. Wickham's plan. I have tried the pea fallow two years after corn, both by cultivating them and sowing broad-cast, the latter moderately, and very thick; but it all would not do, the crab grass, (*Digitaria sanguinalis*,) took possession, and the most indifferent wheat in the field was on the pea land, and no clover followed. In one case I sowed the clover seed, and in the other there ought to have been plenty of seed in the land; but in neither case was there any product. Again, another, and I think a more important objection to N.'s rotation is, there is no time or space for grazing, which with N. I hold to be indispensable on all lands that I have yet seen cultivated; superadded to this, are the objections urged by N. himself—the expense and labor of the pea fallow. Now, as regards the objection urged by Mr. Harrison to the five-field rotation, that it would become too foul, I can answer experimentally, to what probably was advanced by him as an opinion, there is no danger, I can assure him of his land not becoming too foul under that system, but the reverse is the fact, that it is decidedly more cleansing than the old three-field, as the summer fallow is far more effectual in rooting out the briers, shrubs, &c. than winter grubbing and grazing. The fifth year I have found sufficiently cleansing for all good farming purposes. Indeed I think you will find it much more so than the five-field rotation, embracing the pea fallow. The second objection, as suggested by Mr. Selden, I think you will also find a speculative one, as I never sow clover on fallow wheat, and so far I have always had a good crop. But you must understand me, though, all this time as speaking of marled land, as I suppose he was, as our lands without calcareous matter are in the general too poor for good farming in any way.

To the third objection, that of rendering the land too close and compact, by trampling the year before corn, I would say, it will not I think be found to hold good upon trial, as I think, upon such land as N. describes his to be. He will make a decidedly better crop, by grazing than upon a foul field. From some experience in both of the five-field rotations, I should decidedly prefer the No. 2 of N., or Mr. Wickham's. There are two, and only two objections to the five-field rotation that I am aware of, and they might not be applicable to all farms or situations, as to mine; the first is, that of small grain crops following the corn, and the next is, that with me one fifth did not give me pasture enough to enable me to keep stock sufficient for the use of the farm; and if we are to waste as much land in a piny old field, to be called a standing pasture, we had as well make a sixth field, and bring it in regular rotation of cultivation. This latter rotation I think, on lands adapted to wheat, and not immediately available to navigation or to market, is decidedly the preferable rotation of any of the foregoing. If I adopt the six-field system, I would say 1st, corn, 2d, clover sown after corn, 3d, wheat, 4th, clover, 5th, clover, the two last to be grazed but not two heavily, 6th, wheat. By this system one field might be manured annually, and so the whole farm once in six years. As to the quantity of land cultivated, it would be the same with the old or Arator four-field system,

except that there would be one-sixth, instead of one-fourth in corn, and two-sixths in small grain instead of one-fourth, making three-sixths or one-half in cultivation, as in the other. Now locality, nature of soil, &c., must determine every farmer as to the rotation best adapted to his situation and circumstances. But I have no doubt, that upon wheat land the six-field rotation will be found most profitable, and upon all I have no doubt most improving. I am a decided friend to grass and stock. Without the one, we cannot have the other. With good grass we can have good stock with which we can enrich our lands, and give plenty and comfort to all its inhabitants, whether of the biped or quadruped race; and in a little while I know by experience that the *net* return of the long will be better than the short rotation.

Having now, Mr. Editor, answered as far as my experience goes all the queries of your correspondent N., and I dare say by this time you are heartily tired of my prosing, I will subscribe myself, your friend—and a

FRIEND TO LENGTHENED ROTATIONS.

April 9th, 1842.

[If our correspondent had not chosen to withhold his name, he would have been known to be, as we believe, a personal acquaintance and friend of all the individuals whose names he has mentioned, and one who has visited most if not all the farms particularly referred to. But still we think that he is mistaken in regard to some of the circumstances which he supposes to exist, and especially as to the abundance of the means of fertilization possessed or available. But we will not undertake to make the corrections which appear to be needed, lest, for want of proper information, we might also err, and in more important matters. It is therefore left to the farmers named, all of whom have been our much valued correspondents on this general subject, to correct any mistakes deemed in any way important, into which our present correspondent may have fallen.

In respect to the scheme of having clover to follow corn, it would undoubtedly be an improvement of the highest value, if the crop can be rendered at all certain. But, judging from our own experiments of several years' continuance, (as reported formerly in the Farmers' Register,) and which were made in the anxious hope and sanguine expectation of successful results, we greatly fear that this admirable plan of rotation cannot be realized, even on marled lands. But still we are far from desiring to discourage farther and full trials—and shall rejoice in learning that the difficulties and disappointments, to which we were formerly subjected, were not insuperable, and may be obviated by more care and better knowledge.—Ed. F. R.

OPINIONS OF NORTHERN FARMERS CONCERNING LIME.

From the Massachusetts Ploughman.

About the year 1836 or '7, I prepared a compost consisting of 12 loads of peat muck, 4 casks quick lime, and eight loads long manure. On the 20th of June I turned over about three-fourths of an acre of green sward and manured in the hill with the above compost, and planted with potatoes. A more luxuriant growth of vines I never saw, which I attributed to the manure, but have since given the credit to the green crop of grass turned in. Owing to dry weather and early frost the crop of potatoes was rather small. However, I considered the theory on the use of lime well established, not only by the result of my experiment, but I had most of the agricultural papers on my side. The next spring I purchased 50 casks of lime which I used in nearly half as many different ways, the last of which was to place about a dozen loads of lime and peat muck compost around the roots of some apple trees, to prevent the grass from growing, which succeeded to admiration, and this I am convinced is the only benefit I have ever derived from the use of lime as a manure. This is the only essential humbug that agricultural writers who are better versed in theory than in practice have ever fastened upon my shoulders, and probably will be the last for some time to come, for my confidence in what they say is almost entirely lost.

[We congratulate "A Highland Farmer" that he has escaped with so little loss as the expense of 54 casks of lime and the labor of applying it to his fields.

The idea of destroying the whole grass crop under his apple trees by spreading on lime is not bad. Lime will kill the *sward*, the *canker worms*, and the *manure* with which it is mixed—it is much more certain to kill than to assist the growth of vegetation; and if it were not too costly we would recommend it to be spread on thistles, bushes, &c., which are to be destroyed.

In regard to the theories on farming, published by those who have no experience in the business, we are inclined to think that lime will have no effect on them. Their authors have wallowed in lime till their coats are as white as their hands—and still they crawl about and show signs of life, crying lime! lime! They wonder that farmers are so stupid as to doubt the value of lime; yet the only evidence they can adduce in its favor, on our New England soils, is from theorists who have made no actual trials of it.

Ever since we first commenced the publication of the Cultivator we have plainly expressed our own views in regard to lime, and we have called on those who might differ from us to exhibit their evidence in its favor. But we receive *no evidence*. We have *opinions* as thick as cranberries, but no evidence that can be relied on to show the superior merits of lime in agriculture.

Beginners in farming who have no ideas of their own must copy what others have written—they are ambitious of making a noise about something or other and they may as well rant about lime as to bawl in favor of Durham cattle which they are driving about the country for sale.]—*Editor of Ploughman.*

[The first of the foregoing paragraphs is an ex-

tract from a communication to a late number of the Massachusetts Ploughman, and the balance is the comment thereupon, by the editor, who is also understood to be a practical and experienced farmer. The liming farmers on James river might adduce their large experience, and a large part of their present increased productions and profits, as proofs of directly the opposite of the opinions above stated. We had before learned that liming in Massachusetts had been attended with but little profit—for what reason we had too little knowledge of existing circumstances to pretend to determine. But we would not have expected, from any degree of such ill success, whatever, in recent and limited trials of a new practice, so sweeping and general a condemnation of lime as manure, and so dogmatical and entire a denial of good effects, which so many thousands of practical and prosperous improvers have believed in and asserted. It would have been much more like philosophical inquiry, and more likely to be conducive to the profit of the inquirers, to search, by investigation and experiments, for the peculiar circumstances, whatever they may be, which (according to facts stated above) have prevented liming in Massachusetts having the good effects undoubtedly produced by liming elsewhere. —Ed. F. R.]

REMARKS ON THE PRESENT CONDITION AND OPERATION OF THE BANKS OF VIRGINIA, AND THEIR PROSPECTS.

We had designed to state generally the result of the latest legislative action on the banks of Virginia; but that action was not completed until just before the rising of the egislature, and too late for the last number of the Farmers' Register. We shall now give a general and cursory view of the existing condition of things connected with our fraudulent banking system and its operations; which condition will probably remain until new legislation shall vary it, or until the growing distrust of bank solvency, and growing popular indignation and execration, shall operate to close the banks, and put an end, for a time, to the whole system of legalized falsehood, fraud, and villany.

It is not worth while to state particularly what is the purport of the existing banking laws of Virginia, as fixed by the latest act. Indeed, we doubt whether a single member who voted for the last law has any correct or definite opinion of the actual measure of obligation, or of penalty for violation of obligation, now imposed on the banks; or whether any two lawyers, if consulted, and advising deliberately, would agree in opinion thereon. The presidents of the banks in Richmond, it is generally understood, have written the new provisions of indulgence of most or all the bank relief laws that have been enacted since 1837; and at any rate, whether from the restrictions being thus cunningly devised for the purpose of being *total'y inoperative*, while seeming to threaten awful penalties on bank failures and frauds, or whether the stupidity of legislators has alone served to reach this same desired result—it is certain that all legal penalties on the banks are, by various obstacles, rendered totally unavailable to the injured and cheated individuals who would *dare* to seek legal remedy for their wrongs, and for the frauds practised on the whole community. The legislature of Virginia, during its whole course of collusion with and thorough support of fraudulent banks and fraudulent banking, has not ventured *directly* to violate the constitution so far as to forbid individual creditors to collect debts from the banks in any and every legal mode to which other debtors are subjected. But, in practice, the same end is as completely reached. For when the claim for justice is so beset with difficulties and delays, that to obtain the benefits would cost the creditor more than he would lose by the dishonesty and discredit of his debtor, (the bank thus legalized to swindle,) it follows of course that he will continue to submit to be cheated by the debtor, rather than pay double as much to obtain legal redress as his loss so incurred.

The action of the Cincinnati mob, more than the voice of reason or the demands of honesty, caused the legislature of Ohio to compel the banks of that state to resume specie payments forthwith. The distant but plainly audible mutterings of popular discontent and indignation acted powerfully to produce the similar unlooked for events which have since been consummated, of resumption of payments by the banks (or such as did not avow bankruptcy) of Pennsylvania and Maryland. Thus then the sole excuse for continued suspension in Virginia, (which had been relied on solely because it was thought impossible to cease to serve,) was completely taken away. A little time before, it was the universal cry of all the bankites, from the wise, patriotic, moral and religious leaders and wire-pullers, down to their lowest and basest tools and mouthpieces, that "the banks of Virginia certainly *ought* to resume payment, and *could* safely resume, as soon as those of Pennsylvania and Maryland should resume—but not before." Well! instead of suspension being continued in these

almost bankrupt states, as all these bankite arguers or assertors counted on, for five years more at least, (as assured by the previous law of Pennsylvania,) resumption was suddenly and unexpectedly required and enforced; and, as we predicted, not a word more was said by our bankite orators and editors about resumption in Pennsylvania and Maryland being the only requisite for resumption in Virginia. The lie and the fraud had served its purpose up to that time—and the high dignitaries who had used it, and their most slavish and basest tools who had been continually proclaiming this alleged sole excuse and reason for suspension, quietly dropped it and made no more mention of it than if it had never been used at all to ward off resumption of payments. In the bill then before the legislature there was a provision that in case the banks of Philadelphia and Baltimore should resume payment, the banks of Virginia should also be compelled to resume within 60 days thereafter. This provision was *very well* while no such contingency was deemed possible; and would have served admirably to keep up the delusion, and give countenance to the bank falsehood and fraud founded on the suspension of northern banks. But while the bill was yet in progress, the legislatures of these two states actually passed their laws to compel their banks to resume—and our legislature *therefore* at once struck out the provision founded thereon. It could no longer serve its *designed* purpose of deceiving the public.

The recent bank relief laws require the banks to resume payment on the first day of next November. But, unless other extraneous circumstances shall before that time arise to enforce the requisition, there will be no *real* resumption then, but only such pretended and falsely asserted resumption and continuation of specie payments, as existed in February and March, 1841. The branch bank system of Virginia, (which alone would serve to render any banks irresponsible, and therefore corrupt and dishonest,) of itself will suffice to protect the banks from paying any thing worth notice for a month, or for several months. And within one month the legislature will be in session, and ready to grant any desired relief to the banks, and continued indulgence to suspension. Long before November shall arrive, as formerly, the notes of the different branches will be so exchanged that it will be very rare to see any bank note in circulation near the branch where only it promises to be payable. The Wytheville notes will be issued in Norfolk, and Norfolk notes in Clarksburg, &c. The banks will claim not to pay deposites except in "current funds," which term means the worst bank notes that the bank may choose to receive at that time and for that purpose; and though this impudent pretension and claim has no legal validity whatever, still in practice it will be maintained by the banks. Still further, the merchants are the drawers of nearly all the checks presented—and they will draw them only for "current funds." With these several strong means of protection against paying their honest debts, the banks could keep off any considerable practical resumption of payments, as well as they now avoid paying their notes for one and two dollars, which are now by law payable in specie, and which they take care to issue far away from the place of payment.

So it is, and we grieve to admit it—that the banking system of Virginia, as permitted and sanctioned by the legislature, is now more degraded in regard to honesty, and in reputation, than any we know of in all the Atlantic and most of even the western states. And there remains no hope for relief, either in the banks' forbearance to continue their frauds, or in the legislature enforcing sufficient penalties to prevent bank frauds. And full and sufficient causes of this deplorable prostration of the character of this once noble and universally honored commonwealth, are to be found in *the existing partnership of banks and state in the trade of fraud, and the enormous indebtedness of the body of bank directors and also of members of the legislature to the banks.* The reports of the bank committees recently made to both houses of the legislature sufficiently expose these astounding and deplorable truths.

From these reports appear the following important and curious facts; and for more full proof of all, and of more than we have time to charge, we refer to the two reports, and earnestly wish that they could be read by every honest citizen:

That 55 members of the last General Assembly of Virginia were then debtors to banks, in the gross sum of $111,675:

That the bank directors (so far as reported, and the reports not being complete,) were indebted to the banks, as principals and endorsers, individually or as members of commercial firms, $2,321,080, or nearly one fourth of all the capital of all the banks in the state.

The directors of the lately established Exchange Bank deserve especial notice and applause, (considering that they are such new hands at the business,) for their expertness in getting the lion's share of the spoils. The reports to the legislature show the following amount of loans and liabilities:

Capital of the Exchange Bank and its branches, - - - - -	$1,782,037
Loans to and liabilities of its directors	734,930

Or more than two-fifths of the whole capital.

Capital of the Petersburg Branch of Exchange Bank - - -	$475,000
Loans to and liabilities of its directors	$219,606

Or nearly one half of the capital.

But the *crack* operators are certainly the directors of the little Branch (Exchange) Bank at Clarksville.

Capital stock, nominally $200,000, but paid in only - - -	$175,000
Loans to and liabilities of its 7 directors, - - - - -	$233,914
Or more than its whole capital by	$58,914

This we take to be the *ne plus ultra* of what are considered honest banking operations, for the accommodation and profit of bank directors.

Let it be observed that a director might be indebted to half a dozen banks, and no doubt many are indebted to several, and yet no more of his indebtedness appears in this report, than his debt to the particular office in which he is a director. We have known one single family and business connexion to have members as directors in almost every bank and branch in eastern Virginia. As most directors serve, and value their places, *merely* to borrow as much money as possible, it follows of course that they will exchange such friendly favors liberally; and each one who is greedy of large loans will seek them from as many different banks as possible. Thus, independent of all other particular influence, *growing out of family and business connexion*, a bank director has a general claim and influence, superior to other borrowers, in every bank and branch besides his own.

It further appears from the statistical facts of these reports, as drawn from the banks, (and which is precisely such as reason and general truths would have caused to be inferred,) that very few directors have any interest in the banks as stockholders, beyond the exact amount that the law *requires* them to own, to make them eligible to the appointment. This amount is 5 shares—and it is amusing to see in the report how generally each director's stock is of that precise amount. If a single share were enough for that purpose, there would have been as generally no more held. Bank directors are generally well enough informed to know that banking, (as *they* conduct it) is a very bad business for the stockholders—and is valuable only to the *borrowers*. They therefore, for much their greater number, take care to have as little as possible of the stockholding interest, and as much as possible of the borrowing interest in the business. In this town of Petersburg, these truths, (as well as other things important to directors' interest,) would seem to be especially well understood. For of the 21 directors of the 3 branch banks,

1 director, who owns the largest amount, has only - - -	25 shares
2 - - - - own, each,	15
1 - - - - - -	10
1 - - - - - -	7
1 - - - - - -	6
and the other 14 - - -	5 shares only.

The officers (from presidents down to runners included) of the Virginia Bank and its branches, are indebted to them, $36,367, and the officers of the Farmers' Bank and branches, $42,787. This is another powerful influence operating against resumption. The charter of the Exchange Bank prohibited this class of debts, and *therefore* there are none such there to report.

At pages 63 and 64 of this volume, we presented abstracts from the latest official reports of the three principal banks of Virginia, showing some remarkable evidences of the treachery of all these institutions, and the falsehood of the pretension that *they were using the indulgence of suspension of payments to prepare for meeting payment.* In the previous year of suspension, and of asserted and pretended preparation to pay specie at its close, (as required by the then law, and believed in by the duped people,) it appeared from those reports that the proportion of notes in circulation, to coin in the banks, had been *increased* as follows:

	January 1, 1841.	January 1, 1842.
Bank of Va.	$3.10 to $1 coin	3.38 to $1.
Farmers' Bank	3.34 to 1	3.50 to 1.
Exchange Bank	3.53 to 1	2.90 to 1.

And taking a general average, these three institutions had, during that year (1841,)

Increased their outstanding debts,	$667,462,56
Increased their circulation,	380,983,33
Decreased their specie,	27,581,23
Making total increase of liabilities,	
or of greater *inability to pay specie*,	$1,076,027,12

When we first prepared that abstract, the reports of the small western banks had not been published. Their statements are embraced in the later report of the senate, and they vary the above average a little, but not materially. That report also differs from the above, in comparing the time of April, 1841, (date of commencement of the last *avowed* suspension,) with January 1, 1842, or less than the nine last months of "preparation to resume payments;" and the general results are, that all the banks of the state, in that time, had

Increased their discounts, -	$343,016
Increased their circulation, -	859,165
	$1,202,181
Increased their specie, - - -	260,628
Which deducted, leaves of general increased liabilities, or increased inability to resume payments, - -	$940,553

We could defy any bankite to produce, from all the annals of the commercial world, between the early times of the South Sea Bubble and of Law's Mississippi Scheme, and the present and recent time of non-paying banks in America, evidence of such gross fraud, and treachery to trust and to every obligation of law and honesty, as the above statement shows, conducted as this has been by men of the highest respectability, and moreover deemed honorable, patriotic, moral, and many of them also straitly religious!!!

Many other facts stated in these reports, though of less importance, deserve to be noticed, as matters of curiosity, or of shameless abuse.

The cost of all the banking houses in Virginia, amounts to $495,495. When sold hereafter, all these bankrupt palaces will scarcely bring the fifth part of their cost. All their business might have been transacted in apartments costing much less than one fifth.

The salaries of all the officers of the banks of Virginia, amount to more than $200,000 a year, or nearly as much as would have paid the legitimate and proper expense of the civil government of the commonwealth, before the commonwealth had become involved in the trade of banking and in debt.

The amount due from the northern banks (of other states,) to those of Virginia is $207,922, and the Virginia banks owe to northern banks, $411,287.

The bad debts at the Virginia bank at Richmond, as reported by the directors - - - - - -	$178,818
And the doubtful - - -	62,982
And as reported by the stockholders as bad - - - - - -	220,000
And as doubtful - - -	97,000

(Neither including defalcations, or totally worthless stocks, we presume.)

But besides this table, there is another reported by the bank of Virginia, showing the "amount upon which no interest has been paid for the last 12 months," to be $630,551. When interest has not been paid on a bank debt for a year, there is generally not much to be expected of the principal. The Farmers' Bank reports a like item, amounting to $249, 014.

Some *partial* light is thrown upon the gross abuse of long continued "*accommodation*" loans. The Virginia Bank and branches, exclusive of those at Lynchburg, Norfolk, Danville and Charlestown, which made no report, "*owing to misunderstanding the question*," have debts which have been due

More than 10 years, - - -	$305,470
Between 5 and 10, - - -	458,018
Between 1 and 5, - - - -	447,031

Of the Farmers' Bank, there are answers to the question on this head, from only the two branches of Fredericksburg and Winchester. We presume that the president of the mother bank at Richmond also "did not understand the question," and that the branch presidents at Petersburg, Norfolk and elsewhere, were no more acute than their superior in Richmond. To show how much self-interest may sometimes blunt as well as sharpen intellect, we will copy from the report this puzzling question which so many presidents ("learned in the law," too,) and directors *could not understand*. It stands first in the list addressed to all the banks, and is as follows: "What amount of debt is due to each bank and branch thereof, which was originally contracted more than *ten* years past? What amount was contracted more than *five* and less than *ten* years past? And what amount contracted more than *one* year and less than *five* years past?"

One more statistical fact will be mentioned, and which only is not derived from the bank reports. It is that the last known sale of Virginia Bank stock, was at $45 the share of $100 par.

We pretend not to argue with, or to instruct any person who is interested in sustaining the banks in their course of fraud; nor any of the many true and honest men whose understandings have been so clouded by bank delusions as to believe that the system is honest and beneficial in its present operation. But, of those who admit the evils and the vices of the banking system of Virginia, and sincerely desire to have them reformed, and who have vainly counted on and waited for those persons having power to reform these institutions, we would ask, what possible ground can there be for such hope from bank officers and directors and from legislators, acting as they have done now for five years, and under influences which still exist? We entertain no expectation of either voluntary or legally coerced reformation. Nevertheless, we have full confidence that either the reformation or the destruction of the fraudulent system *will* come, and *soon*. The banks are taking their full swing of allowed

iniquity. Their directors and users foolishly believe that that is all which is needed to sustain them. But they will find their mistake. The growing depreciation of the notes, the still faster growing discredit and distrust of the banks themselves, the daily growing abhorrence of the whole fraudulent paper money system, and of the conduct of it in Virginia in particular, will all concur to demand and enforce resumption before the laws will *in good faith*. And as we believe that *bona fide* payments cannot be resumed and maintained by banks so crippled, and so deservedly discredited as those of Virginia are and will be, the forced attempt at resumption will most likely produce a final suspension, which will be then called by the true name for all bank suspensions—that is *bankruptcy*. If we are mistaken in the degree of peril of such results to the banks, or as to the time, we cannot be mistaken in this opinion, that the longer they postpone resumption, the greater will be the danger of undisguised bankruptcy from the attempt. Banks of circulation, if paying, cannot stand except when sustained by public confidence—and the banks of Virginia have so acted as to forfeit all claim to trust and confidence.

And now, when all the evils of the previous full sway of the fraudulent paper system are about to be brought upon the whole community—evils which we predicted long ago, and vainly tried to warn the agricultural community against—the cry is raised by the bankites, and will be sounded and echoed much louder yet, that the movements for bank resumption, and the action of opposers of the frauds of the banks, have caused the present and still growing distress. It would be as just and true a charge if all the wretchedness of feeling, prostration of powers, and acknowledged ruin, of a newly sobered drunkard were to be ascribed, not to his intoxicating draughts, or to his having been drunk daily for 10 years before, but to his *finally forced* state of abstinence and sobriety. It is very true, that no improvident debtor can pay his debts without inconvenience or privation—and we have never deemed as a light matter the enormous load of bank debt on the people. But debtors who will not prepare for the inevitable approaching, though distant day of payment, until forced, are generally such as would suffer the less by being thus forced to pay early rather than late. Those earlier debtors who have remained in debt to the banks during the whole past five years of suspension, and are not yet prepared to pay, *never will be prepared*. They are ruined already, or their ruin is inevitable, from their own imprudence; and no greater extension of indulgence can possibly save them. And those who have first contracted standing debts to the banks, during the time of suspension, have been therein no less imprudent, are not the less hopeless, and have no claim whatever that the public should remain under all the burdens and evils of a debased paper currency, until these new and fully warned debtors shall voluntarily retrace their false steps. If there had been any *real effort* made, either by the solvent debtors of the banks to pay their debts, or of the banks to prevent new debts and liabilities being made, the improper excess of debts might have been paid, and all impediments to resumption of bank payments would have been removed, and bank payments honestly and truly resumed, three years ago, and without any serious loss or inconvenience to the country—indeed very far less than has been suffered since, by the continuance of the fraudulent operation of non-paying banks. If great and general pecuniary distress be now pressing on the people in general, as well as on banks and their debtors, and if the pressure should cause ever so much decline in the selling prices of property, it will not be caused (as alleged by the bank organs) by measures for bank resumption, but because of the *long continued delay of resumption*, and the *total failure to prepare for resumption* both by the banks, and their improvident and reckless debtors. These deductions are so plain that they require merely to be announced to obtain the assent of unprejudiced persons. But if any such reader should still believe the current assertion, that it is bank reform, and not past bank abuses (as *we* use the term,) that causes distress, we ask what caused all the commercial and general pecuniary pressure in Virginia in 1841? During that year, as before shown, there had been no contraction of bank loans and issues, but on the contrary an actual increase of issues and of liabilities, to the amount of more than a million of dollars. Surely this reverse and adverse operation to resumption of payments ought to have prevented distress, if contraction and resumption, properly and gradually conducted, would produce greater distress. And the approach to resumption might have been abundantly slow, and yet have been safely reached by the banks before 1840. Resumption of payments, so reached, would have been better for the debtors themselves—better for the permanent stockholders, (not stock-jobbers,) by showing them earlier the true state of their wasted funds—incalculably better for the commonwealth—and better for all, except bank officers and the *borrowing and speculating and bankrupt* interests, to whom bank loans are "the breath of their nostrils," and who must cease to exist when deprived of that sustenance. It is this class that has long directed the banking policy of Virginia,

and governed the state. Its power and action even now are fearfully strong, and are dealing blows of destructive force. But they are but as the dying struggles of the hooked shark, which will soon be quieted by the death of the insatiable monster.

And now, so far as we now know and expect, we shall take leave of this subject—deeming that we have already rendered all the service in this respect to the agricultural interest, and the country, that is in our power. Nor do we believe that our labor has been vainly exercised to expose and to assail the fraudulent banking system, through this, and still more through other publications. The seeds which have been thus sown have not perished; and however little outward show there now may be of growth, the crop will yet be abundant, and the future harvest certain. Within a few years, at farthest, the fraudulent banking system of Virginia will explode, and the fraudulent principle of the system will be universally acknowledged. And, whether such be the result or not, it will be always one of the things of which we shall be most proud, that all our powers, such as they are, have been zealously exerted, though almost unaided and alone, to expose and to contend against this most iniquitous and infamous system. All that we have done, and freely and gratuitously paid, and risked the loss of, for this object—and the meeting and suffering of all the falsehood, slander, and every other act of maligant hostility of bank partisans and bank slaves, that have been brought in vain to bear us down, all will be deemed a cheap price paid for any forwarding of the final overthrow of the fraudulent paper system.—Ed. F. R.

REMARKS IN REPLY TO INQUIRIES AND STRICTURES

On an "Essay on the making, the preserving, and the applying of manures."

For the Farmers' Register.

In the number for March of the Farmers' Register, p. 100, is a neat little modest piece, signed "A Young Farmer," in which the writer of a certain essay on manures is called on to answer certain inquiries. I now avow myself as the author of that essay. For certain reasons, which even now I am not at liberty to disclose, the essay appeared, contrary to my usual wont, in an anonymous form. I greatly prefer that the productions of every man should appear with his own name appended thereto. The little that the "Young Farmer" has been pleased to tell about himself, has prepossessed me much in his favor; and I hereby invite him to pay me a visit, when I will with much pleasure more fully satisfy him on the queries propounded.

In the mean time, I will say that the above essay is founded, *in the main*, upon practice, and not upon mere theory. I intended it as a practical illustration of my own mode in making and applying manures. If the piece has any merit at all, it is this latter feature which has given it its value. The only part of the essay which has not been carried into practice, and I think *successful* practice, by myself, is that which relates to manuring by confining cattle in moveable pens. For certain reasons, which it would be tedious to explain, I think it to my interest to keep but few cattle, only enough to consume the coarser offal of my corn. But were I more remote from market, I should certainly go largely into the cattle business, restricting the number only by the amount of food I could raise for them; and this I would do, in a great measure, for the large amount of manure they would enable me to make. Having then a large number of cattle, as soon as their shelters ceased to be necessary I would begin to pen them every night, and continue the practice, until the severe weather of winter would make it proper to collect them under their shelters again. How large these pens ought to be, and how long the cattle ought to be confined to one spot, must depend, as I state in the essay, on the number of cattle kept. In this way all the manure, both liquid and solid, would be collected; nor do I see why it should not be as permanent as when removed from the farm-pen. In my own case, I never confine my cattle, except on the farm-pen and in their shelters, and the sole reason is, that I have too few to make it an object to resort to moveable pens.

As to the inquiry about hogs, I would answer that the close confinement to which I subject mine is the result of necessity, not of choice. The same reasons which influence me to keep but few cattle, induce me also to confine my hogs. My farm is situated very near a good market, and is so small that I can allow no part of it as pasturage, either for cattle or hogs. Every foot of my land is constantly in some crop, either for home consumption or to be disposed of at market. Under these circumstances I resort to soiling, and in other respects make my stock as comfortable as I can. But it would add much to their thrift, if, in addition to their other care, I could allow them, particularly in warm weather, the indulgence of pasture, shade and running water. But notwithstanding these privations, I hesitate not to say, that under my care "they do thrive through our long, hot and dry summers," so that they are a source of considerable profit to me, and I see no reason why they should not be still more profitable to those who are in circumstances to allow them greater advantages.

The "labor necessary to collect materials for them to work up into manure" is, when properly fixed for it, not very considerable. The materials are fully explained in the essay. I will now add that they are collected in the winter, when work is not very pressing; after showers of rain when the ground is too wet to stir it, and at such other times as we find most convenient. Such opportunities are taken to store away large amounts, and then the labor of distribution is very trifling. This manure, though "mixed with large proportions of mud, dirt and litter," I consider as very valuable, particularly for corn, the great favorite of the hog. Its value would be much increased,

if to the mixture were added small quantities of lime, or larger quantities of ashes. I would not advise carrying it immediately to the field after removing it from the pen, but let it lie in heaps of 50 or even 100 bushels, until it becomes dry and comparatively light. In two or three months, and sometimes earlier, the vegetable matter will be pretty well decomposed, so that in digging into these heaps the whole will be found in a friable state, so as to crumble by the mere act of casting it into the cart. I now consider it as fit for use, and the next operation is to carry it to the field, where I find it of great service.

The next query is, "What will a farmer's pork cost him raised in this way, out of the immediate vicinity of a market?" To this I reply, that the cost of pork, either near to market or remote from it, depends very much on the following particulars: the price of corn, the thrift of the hog, the care that is taken of him, the quantity of food other than corn that is provided for him, and the constant economy with which he is fed, so that he will always have enough and waste nothing. My pork costs me, according to the best estimate I can make about $4 the 100 lbs.; and if the hog be a *thrifty* Berkshire—(and there is a great difference in the Berkshires,) about half that sum. In this estimate I take into the account the carcass of the hog and its cost in corn alone; for his extra food, care, &c., I consider as amply paid for by his manure.

But this subject is becoming irksome to me; not that I consider it unimportant, but simply because I have had occasion to write so much about it. I must therefore refer "A Young Farmer" and all others concerned, to a series of essays, which I wrote for the Southern Planter, and which appeared in that work in the volume for 1841. Mr. Charles T. Botts, the editor, will cheerfully (on forwarding to him a dollar) send the volume as directed.

"A Young Farmer" inquires, lastly, "What will it cost per acre to cut down the weeds, &c., for litter?" I answer, that in harvest mowers *here* also demand and receive one dollar per day. The usual task for a mower is one acre. But it is to be recollected, that the weeds are usually cut the latter part of September, or first of October, when the days are much shorter, and consequently the wages ought to be less. This work is commonly done by my own laborers, (for I sow no wheat,) and they do it immediately after gathering the fodder and cutting the tops. I once hired and paid 75 cents per day; but now I could get it done cheaper. But were the cost even greater, still I should feel myself amply compensated in collecting the weeds. I find they make the speediest, the richest, and the very best manure. The mules, the cattle, and even the hogs, eat them with avidity. In addition to this, there is a great convenience in having them stored away ready for use. In summer, when the crops are on hand, stables, hog-pens, &c., are often neglected, because we cannot spare time to send to the woods for litter; but here are the stalks of weeds which have been reserved for this very emergency, and it requires but little time in the morning or evening to distribute them. Thus, whilst the crops are busily engaged in exhausting the fields, the hogs, horses, &c. are as busy in manufacturing manure to repair the injury.

Connected with the above, there is one more inquiry still more important. "Is not the practice (of removing the weeds) injurious to the land from which they are taken?" This is very generally considered to be the fact, and at first view would seem to be the case. But after looking at the subject in all its bearings, I am decidedly of a different opinion. Now I do not pretend that the removal of a weed, or any thing else from the land, can benefit the spot on which it grew. But what do we accomplish by it? We produce an easy and convenient material, by which, even at the busiest seasons of the year, we can keep our stables and hog pens clean and healthy; and after answering this very important purpose, it answers another, if possible, still more important, it makes the richest and best manure. Then it cleanses the field, leaving it in a situation, in which the crop of young clover or other grass may make the greatest progress: and at the next harvest, instead of battering the scythe against hard dry weeds, there is a beautiful clean surface to cut over. Labor therefore is saved, and the crop secured is cleaner and in better condition. But what becomes of the weeds in the mean time? They are lost, it is true, to the spot from which they were taken, but they are not lost to the farm. After being charged with Liebig's ammonia, and other enriching properties, they are carried back to the field, and instead of *standing* here and there at intervals apart, or of *lying* thin, covering so large a space as to do almost no good, they are concentrated so as to display all their beneficial effects. And now I appeal to "A Young Farmer," and all others of equal candor, if weeds thus treated and used are not made to answer a more valuable purpose, than when left to injure the hay crop, or to fall and lie thin on the land?

And now having answered the inquiries of "A Young Farmer," whom, if he will allow me, I will call my friend, I must take a reluctant leave of him. But I hope to hear from him again over his own name. A mind so inquisitive as his cannot remain inactive, and when employed about farming, the first, the greatest and the best art, must lead to valuable results. But there is another correspondent in the same number (page 136) to whom it would be very uncivil and uncourteous in me to fail to pay my respects. And I take it as a very civil thing in the above correspondent, that he has had the candor to append his name to his communication. If Mr. Nicol will take the trouble to look to the end of this paper, he will also find my name there; and I now inform him, that the reason why the essay commented on by him appeared without a name was, not that I was ashamed of the piece, or wished its faults to be charged to another—not that I felt myself unable to sustain every position there taken, but simply for reasons which I shall not be at liberty to disclose till the meeting of our Agricultural Society, on the 25th day of May next. If Mr. Nicol will favor us with his company on that day, I will with much pleasure satisfy him on this point.

I proceed to consider this gentleman's strictures on my essay. "Passing, (says he,) over the preliminary observations of the writer I will begin with his stable management. I am not aware that any farmer or owner of a horse, who

pays a due regard to his own interest, the health and comfort of his horse, or to the most economical mode of making manure from that source, is in any doubt as to how long this (stable) litter ought to accumulate before it is removed; and that is, that it should be removed every day. The writer of the essay is, however, "of the opinion that it ought to remain until by its great heat it endangers the health of the animal." On this, I remark, that in the above sentence, I have been very unfortunate. I labor under the misfortune of not being understood. Now I acknowledge that it is one of the first requisites of a writer or speaker to make himself understood. In this instance, however, I am so unfortunate as to have failed. At this, I confess, I am a little surprised; for I used neither Latin, nor Greek, nor Hebrew, nor any other dead language, but the plain *living* English, and that too of the simplest kind; and yet Mr. Nicol has failed to understand me? He seems to think that the danger in the case must necessarily go so far as actually to *produce* the apprehended evil. Now I never intended to convey any such idea, and I did suppose that I had sufficiently guarded against any such construction, by what appears in the sequel. I intended that the litter should accumulate, and the decomposition go on, until the point of danger was reached, and then arrest it, by removing the whole mass. In the case of my "stable management," we will suppose that the heat increases, until a careful vigilant master sees that the apprehended danger will soon issue in the evil which he wishes to prevent, and promptly takes measures to arrest it; what misfortune, let me ask, can ensue in this event? Danger was *incurred*, it is true, but a timely preventive was administered, and therefore no evil ensued. But what is the object of supplying a stable with litter? It is, according to my theory, two-fold, first, to promote cleanliness, and second to increase the amount of manure. And now the whole matter is narrowed down to this one point. By what management can manure be most rapidly increased? Is it, by daily throwing it out in small quantities, as Mr. Nicol supposes every body does, there to be evaporated by the sun, or washed away by the rains, or torn to pieces by the hogs? Or if the hogs will let it alone, till it accumulates to a large amount, still to let it remain there, until full one half its virtues are destroyed by fire-fang? Or is it, to let it lie in the stable as I recommend, and, as I think, common sense recommends, safe from the sun, from the rains, from the hogs and fire-fang, until the health of the horse begins to be in danger, and then immediately remove it for use?

But on Mr. Nicol's plan, permit me to inquire, what becomes of the *liquids*, which according to late scientific authority is the very best part of manure. According to Liebig, who by the best farmers of England and America is now received as a standard authority in scientific agriculture, it is the ammonia which gives its chief value to manure, and this property is derived mostly from the urine. But from any thing that appears in his strictures, Mr. Nicol lets the whole of this run to waste. There is no litter to absorb it, for it is all thrown out every day, nor is there any cistern or tank to collect it. This important article, then, imparting its chief value to manure, is, according to this wasteful farmer's plan, wholly lost. No wonder then (see page 99) he had to apply such very large quantities of marl, and of burned shells, to keep up the fertility of his land. Any man who will submit to such a waste at home, must resort to a large amount of foreign material to supply the deficiency. In my stable, I am happy to say, there is no such waste. The liquids are collected, and the solids are preserved; and this is done, whilst the health of the animals is carefully preserved.

I am truly sorry that my mode of pen-feeding cattle, comes also under the ban. To this plan, Mr. Nicol objects, because he "has never yet been able to secure that amount of cleanliness so desirable to the health and comfort of the animals so fed." As a set-off to this, I remark, that I have never been able to secure health and cleanliness on any other plan. This very season, I wished to make a beef of one of my steers, and that he might enjoy every advantage, I confined him to a stall. I gave him frequent supplies of litter, and at length was compelled to adopt Mr. Nicol's mode of daily throwing it out; but still every morning one flank and thigh of the poor beast was comepletely covered with his own filth. Whilst this was the case, the cattle that lodged in the pen, or selected their own place under the shelter, were quite clean. Besides, if Mr. Nicol will favor me with a visit, and I should be very happy to see him, I will show him what it seems is a stranger to him, a *clean* farm-pen. But fearing that he will not accept my invitation, I will tell him what sort of a farm-pen I have. It is situated on a gentle declivity, with a bank on the lower side, and through this bank is an aperture, which I can open or shut at pleasure. By shutting I retain the fluids, and by opening I can discharge them, when they become excessive. Now by this contrivance, and by what I speak of in my essay, large supplies of litter, (I mean large for a small farm,) I actually have a clean and comfortable farm-pen; and if Mr. Nicol will fix his farm pen in the same way, I venture to say that he will have cleaner and better contented cattle than he now has, when confined to their stalls.

But he also reads me a lesson about my hogs, and thinks my mode "of feeding will not suit the judicious hog breeder." When I came to this sentence, I was at once fully convinced that Mr. Nicol did not know against whom he was hurling his shafts. Why, sir, the hog business is my strong forte. If I excel in any thing, it is the skill with which I manage my hog department. My piggery with its inmates is the admiration of the whole country. It is well worth a trip from Sandy Point to visit it. I have just sold a fine young Berkshire boar just eight months old for $55, a pretty good price for a small farmer these hard times. I still have fine boars and brood sows, and thrifty shoats, and promising pigs. One word more; my neighbors will *laugh* at Mr. Nicol if he attempt to give me any more lessons about breeding hogs. With these remarks I dismiss all that he says about my hog-management.

But, as it appears to me, he is a little anxious to turn me into ridicule. Hence (page 137) he says, "I would ask the writer, when is manure thoroughly, properly, fairly, fully made?" Now I was not aware, till I saw all this array of epithets brought together, that I had made use of

one half of them. I must have had a kind of presentiment that I was writing for just such a person as Mr. Nicol implies himself to be, one who finds it difficult to comprehend. For to show what I meant by manure fully made, I unconsciously used no less than four different epithets all pointing to the same thing. Hitherto I have taken to myself no credit for any thing except my hog-management. Now, I begin to think, I deserve some credit for my ingenuity in avoiding the figure of speech called tautology, which is so offensive to every correct writer; for the terms thoroughly, properly, fairly, fully, though they *point* to the same thing, do not *mean* precisely the same thing. Now I will venture to say, that there is no farmer, great or small, young or old, who honored my essay with a perusal, but fully, thoroughly, fairly, properly understood its meaning—Mr. Nicol always excepted. But I really wish to enlighten him also. I shall begin to think much less favorably of myself as a writer if there be a single reader who does not *fully* (I beg pardon for using this word) understand me. I will again look over his piece, and see if I can find an easier term. I see he uses frequently the word "decompose." I will employ this, and see if I can make my meaning clear. By manure fully, &c., made, I mean vegetable matter which when mixed with animal excrement has undergone decomposition, so that the vegetable fibre is destroyed, and is reduced to a state of rottenness. When I find vegetable matter of any kind, leaves from the woods, wheat straw, corn stalks, weeds from the field, or any thing else in this state, I call it manure; and I consider it so valuable that I wish I had thousands of it on my little farm at this time.

But I am again incurring my common fault, making my paper too long. There is however one more point or which I must pay my respects to Mr. Nicol. At the close of his strictures, he says, "I have seen finely rotted manure, dry straw from the stack, and dry and recent leaves from the woods, applied to clover side by side, and the best results were from the covering of dry straw. I have also seen young wheat top-dressed with pine leaves (on marled land) with benefits, though of course less in degree, as distinctly marked as I have ever seen from the application of rotted stable and farm-pen manure." Now, let it be understood, that in commenting on and objecting to the above passage, I do not call in question a single fact there expressed; nor do I doubt that the writer firmly believes all he states. But does he mean that "dry straw from the stack and dry and recent leaves from the woods," remaining and continuing dry, will have a better effect on clover, than will rotted manure? I do not wish to do the writer the slightest injustice, but this really seems to be his meaning. The straw and leaves, it is true, were dry when applied, but they soon became wet, and the young clover having itself a great attraction for moisture, soon covered them, so as to screen them from the evaporation of the sun, and thus, being in a state of continual moisture, they underwent a rapid decomposition. In this process the gases were evolved just in the position and at the time to benefit the clover. Whilst this was the case, the rotted manure, made on the wasteful plan of Mr. Nicol, deprived of its valuable properties, remained there almost in an inert state; and this is the real reason why his straw and leaves produced a more beneficial result than his rotted manure.

There are some other matters on which I intended to comment, but this must do for the present. Whether I shall take them up hereafter depends on circumstances. J. H. TURNER.

ANOTHER MODE OF KEEPING SWEET POTATOES.

To the Editor of the Farmers' Register.

Prince George county, Va., April 8, 1842.

Having made an experiment in keeping sweet potatoes which has proved highly satisfactory, I think it might be advantageous to many of your numerous readers if they would adopt my plan, which is this, viz.: I selected a dry spot, around which no water would remain, and had the sills of my house (ten feet square) placed flat on the ground. I then had the earth dug out to the depth of 2½ feet, and as the earth was thrown out I had it thrown around the sills so as to raise it to a level with the top of them, and sloped off gradually, to turn the rain water falling from the eaves entirely away from the house. I then had the rafters, 2 by 6, nailed to the sills, and the gable end studs, also 2 by 6, fitted from the sills to the rafters; and the whole closely planked on the inside, and as the outside planks were nailed on I had the space between (which of course was six inches) filled in with earth, so that the air was entirely excluded, except at the door. I had two doors made, one to hang on the inside, and the other on the outside, so as to fill in between them with straw or pine leaves, if the winter should be very severe; but I used only the outside door, the winter having been so mild.

When I put my potatoes away, I had some old slabs placed at the bottom of the house, and then a layer of pine leaves, on which I put the potatoes, and after they were all put in, I had them covered thickly with pine leaves.

The eating roots were separated from the plantings, so that we might go in at any time, and get such as were wanted. They were put away on the day they were dug, and we got out such as were put away for eating, every day until some time in February, at which time the eating roots were all used, and I do not think one peck had rotted, out of about 30 or 35 bushels.

The plantings (which I took out a few days ago) also kept remarkably well. The only rotten ones which I saw seemed to be around the edges, where the mice had burrowed under the sills, and caused the dirt to fall in upon them. The mice were quite destructive to them in consequence of having no underpinning and floor, by which they may be effectually excluded.

I had one barrel filled with a particular kind, which I wished to keep separate from the others, and in this barrel I saw scarcely one rotten potato, although the mice had eaten nearly one third of them.

As this was only an experiment, I would not incur the expense of underpinning, &c.; but as the result has proved so satisfactory, I intend to have the house underpinned, and a brick floor laid in

strong mortar, to prevent the mice from getting in.

I have no doubt that saw-dust would be preferable to earth for filling in between the rafters, &c., as the timbers would be less liable to rot, and the saw-dust, (if packed in closely,) would as effectually exclude the air, and at the same time have a tendency to absorb any moisture arising from the potatoes in going through a sweat.

The greatest advantage in this plan is that you may get your potatoes to use just when you please, without the fear of having them injured, except in the severest weather in winter, during which time I think it might prove injurious to open the door at all, except in the warmest part of the day.

J. H. Battle.

OF MIXED EARTHS AND CREEK MUD.

From the Transactions of the Society for Promoting Agriculture in the State of Connecticut.

What experiments have been made of creek or harbor mud from the sea flats? what of mud taken from fresh-water ponds? what of the soil taken from swamps overflowed? How have they been used? on what soils, for what crops, for what grasses, in what manner, in what quantities, and what advantage has been derived from them?

Mr. Belden, of Wethersfield. A piece of land in my neighborhood was manured with earth that had been leached to make saltpetre—the earth had been leached ten years before—the land has borne surprising crops ever since this earth has been applied. I have never witnessed so great and lasting effects from any species of manure.

Mr. Hart, of Berlin. One of my neighbors carried on to his upland mowing a number of loads of earth from under an old barn. It has improved his land surprisingly. For several years the crop has been very great.

Mr. Abel Bronson of Waterbury. I have tried the earth, taken from the ditches in my meadows, but never found that my land received any benefit. I have carried large quantities into my hog sty and barn yard, in autumn, and in the spring have manured my Indian corn with it. I have found a load of this mixture of the earth and manures, as beneficial as a load of unmixed manure, from the barn yard or the sty. I have used the mixture, when it has lain in this situation a year, and never found any dung better.

Of yard or stable dung—tanner's bark, &c.

What methods have been taken to augment the manures taken from the yard or stable? What means have been found to succeed best for that purpose?

Mr. Andrew Hull, Jr., of Cheshire. I have found no manure so beneficial, on poor land, for potatoes, as the droppings of the cattle intermixed with straw, thrown into the yard to make manure, even before it is matured.

Mr. Abel Bronson, of Waterbury. I have thrown pumice, tanner's bark, &c., into my hog sty, and found them to become very good manure.

Mr. Blakesley of Plymouth. More than twenty years past, I had a large nursery of fruit trees. To prevent weeds, &c., from growing, I covered the ground over with tanner's bark. It prevented every thing but the trees from growing. After some years had elapsed, when the trees had all been taken from the nursery, I sowed the land with oats and clover. The oats were good, and the clover excellent. Since the clover has gone out, the natural grass has come in, and the land has continued as good as any I have. I have found bark one of the best kinds of manure.*

I find, from experiment, that two loads of dung, carried on the land in the spring, are worth three loads carried on in the fall.

Ploughing in of clover, or buckwheat.

Have any experiments been made of manuring land with clover, buckwheat, or oats turned, or ploughed into the earth before they were ripe; and has any benefit been received?

Mr. Hart, of Berlin. I have made an experiment in ploughing up a field, on which I had two years before sown clover. The clover was mowed and yielded a good crop. Soon afterwards I ploughed the field and let it lie until I found that the clover had matured. I then ploughed it again. The land looked very well, and I supposed it much enriched. I sowed wheat, but was disappointed in it, for the crop was poor. I knew, however, that the land was much enriched, and concluded that I was prevented from having a good crop of wheat from other causes than the land not being well prepared.

Mr. Phelps, of Simsbury. I ploughed up a clover field, the second year after it was sown, when the roots were full grown. It was about a fortnight after mowing the land. I let the field lie in this situation about six weeks, then harrowed it well—sowed it with wheat, and ploughed in the wheat. The next year I harvested as much as twenty bushels to the acre. The soil was rather dry and sandy.

Mr. Hooker, of Farmington. I sowed a sandy field with buckwheat. When it was grown and in bloom, I ploughed my field in ridges, and covered the wheat. After it had lain about six weeks, I ploughed it again in ridges, putting the new ridges where the balks were before. Soon after I harrowed the field, and sowed it with wheat. The next summer I harvested an excellent crop.

Mr. Belden, of Wethersfield. I have sown buckwheat, both on sandy land and on loamy land, and ploughed it in to prepare the land for wheat. I have had good crops from it, and have found the experiment to succeed to my wishes.

SUGAR FROM CORN STALKS.

Extract from an editoral article of the New Genesee Farmer.

Another great article of product spoken of in the report,† is that of sugar from corn stalks. "A new mode of raising corn, trebles the saccharine quality of the stalk." This is certainly an extraordinary discovery. The stalks of corn, if

* Tan bark is injurious to soil before it rots; then it is excellent.—Ed. Gaz.

† Of the Commissioner of Patents.

gathered before the ear is formed, it is here stated, yield of saccharine matter three times as much as the beet, five times as much as the maple, and fully equal, if they do not exceed, that of the ordinary sugar cane in the United States. "One thousand pounds of sugar, it is believed, can *easily* be produced from an acre of corn. It has been ascertained, by trial, that corn on being sown broad cast [and so requiring but little labor, comparatively, in its cultivation,] will produce five pounds per square foot, *equal to* 108 *tons to the acre for fodder in a green state*; and it is *highly probable* that when subjected to the treatment necessary to prepare the stalks, as above described, in the best manner for the manufacture of sugar, a not less amount of crop may be produced. Should this prove to be the case, *one thousand weight of sugar per acre, might be far too low an estimate.* Should the manufacture of sugar from the corn stalks prove as successful as it now promises, enough might soon be produced to supply our home consumption, towards which, as has been mentioned, at least 120 millions of pounds of foreign sugar are annually imported, and a surplus might be had for exportation."

These statements may well be called startling; but we must be pardoned if we consider them, in some measure, of the *multicaulis* variety. We have a high respect for Mr. Ellsworth; we believe there is not a better officer in the government; and that no man living would be more reluctant to make a misstatement than himself. But we want a good many more facts and experiments in the case, before we can yield entire confidence to such predictions. The whole, for aught that appears, grows out of a statement of a Mr. Webb, of Delaware, given in our November number, who obtained from a small piece of ground at the rate of 100 lbs. of sugar to an acre, and who states that further experiments showed conclusively that the produce *might* be increased ten-fold. Now we have no desire to question Mr. Webb's veracity; but it will be observed in the first place, that he has not yet obtained 100 lbs. to an acre, but only at that rate; and in the second place, that although experiments to him have conclusively shown that a thousand pounds may be obtained to an acre, yet we do not know what those experiments were, and the conclusion is matter of inference or private judgment. We shall be exceedingly glad to be set right on this subject.

The calculation of producing green corn fodder at the rate of 108 tons to an acre is, we believe, more easily asserted than proved. We should like facts in this case much better than conjecture.

Tall meadow oat grass has yielded, green, at the rate of 16,335 lbs. per acre, and dried, 5717 lbs. Millet has yielded, green, at the rate of 12,251 lbs. per acre, and when dried, 4747 lbs. Herdsgrass, when green, 40,837 lbs., and dried, 17,355 lbs., or when cut after the seed is ripe, 19,397 lbs. A crop of herdsgrass producing when cured 17,355 lbs., is indeed enormous; and what very few among us have ever seen, less than five tons being the largest measured crop which has come within our knowledge. We have never known a crop of green corn fodder weighed, when cut for fodder, but we have given in our last No. the weight of an acre of corn fodder of the gourd seed variety, when cured, including husks, and yielding 66 bushels of grain per acre, and the whole amount of that was 2 tons, 13 cwt., 13 lbs. In the case of herdsgrass, the proportion of green weight bore to the dried as 40 to 17 or as 20 to 8 tons. If we may infer any thing from this fact in regard to Indian corn, we may reckon the green fodder from such a yield of corn as 6 to 7 tons. It would, however, be much more than this, if the corn had been sown broadcast; and perhaps may be quadrupled. Conjecture, however, is idle in a case where, we hope, we may soon have facts. It is supposed in the case of the report, that the corn is to be sowed broad cast and yield at the rate of five pounds to a square foot. This is a remarkable calculation; and if corn is sowed thus thickly, how is it to be got at to pluck off the ears, which is said to be a necessary part of the process? A few months however, will settle this; and if an acre of corn, by the mode described or any other mode, can be made to yield five hundred pounds of sugar, we shall throw our hats up as high as any one in the crowd.*

SOMETHING ABOUT WESTERN PRAIRIES.

By Solon Robinson.

Extract from the American Agriculturist.

I am sorry that I am not able to answer the second question, even satisfactorily to myself. But who that ever undertook, ever satisfied his inquirers as to how a prairie looks, while in a state of nature. The reason is that there is nothing analogous, to which one can compare it, in a thickly settled country. But suppose that the reader fancies the country with which he is best acquainted in an old settled country, entirely destitute of buildings or fences, or in fact any mark of civilization, with all the hills reduced so as to make a gently rolling surface, the woodland to remain as it is, and the entire surface of cleared land covered with grass—that upon the upland thick and short, and in the low lands one or two feet high, and in the swamps four or five feet, and he may have a very faint idea *how a prairie looks.*

So you see they are not so "very level." Gently undulating, applies to all prairie countries within my knowledge. Sometimes, though rarely, hills occur that are too steep to cultivate conveniently, and sometimes rocky bluffs. But a general characteristic in this region is destituteness of stone, except a few boulders of granite, that have come from parts unknown.

The streams are most generally muddy bottoms. The timber in the groves or islands that abound throughout this sea of grass, is most commonly short, and grows thin upon the ground,

---

* Since penning the above, we have seen it stated in some exchange paper, that forty tons of green corn fodder were obtained from an acre in Worcester Co. Mass.; and at a late agricultural meeting in Boston, the editor of the New England Farmer is reported in the Ploughman to have said that he understood that 100 tons of green corn had been cut from a single acre at three cuttings, in a season, and he had known 37 tons cut on an acre at one time.

We have no disposition to impugn these statements in the smallest measure; but we should be exceedingly glad to know when and where these crops were produced; and how and when the amount was ascertained.

without underbrush, except at the edges, where the hazel bush seems to be the advanced guard, and is constantly encroaching upon the prairie. There are large tracts of timber land called "barrens," which are about half way between prairie and timber land—the tree standing apart like an orchard, and the ground covered with grass, the sod of which is much less tough than that on the prairie.

One very prominent feature of a prairie, I should mention, and that is the constant and ever varying succession of flowers from spring till fall.

A singular and false notion prevails about the height of the grass, and that it must be difficult getting about. It is not even difficult for a sheep, as the grass never grows high enough upon the dry land to impede or hide them. Near the banks of streams, or in marshes, it is like going through a field of oats or wheat. And it is in such places that grass is cut for hay—some very good—some good—and some that the less said about the smaller the sin committed.

But as for pasturage, no country can excel this. The milk, butter, cheese and beef attest the rich juiciness of the feed. But we lack the beautiful blue grass pastures of Kentucky, for fall feed. Even now, near the middle of December, notwithstanding we have had a hard fall for this country, this grass is green and good. Even timothy or red top would yet afford "a good bite."

The next wonder is about ploughing. And if, my dear reader, you who have ploughed so many acres of greensward with old "Duke & Darby," could only see a "prairie team," you would wonder still more.

Fancy upon a level smooth piece of ground, free from sticks, stumps and stones, a team of four, five, or even six yoke of oxen, hitched to a pair of cart wheels, and to them hitched a plough with a beam fourteen feet long, and the share, &c., of which weigh from sixty to one hundred and twenty-five pounds, of wrought iron and steel, and which cuts a furrow from sixteen to twenty-four inches wide, and you will figure the appearance of a "breaking team" in operation. If you ask me if this is necessary, I can only tell you that I suppose it is, for it is *fashionable*.

I do believe though, that a smaller plough and less team would be better for the land, though it is said it would be more expensive ploughing. It is true that the sod is more tough than can be believed by those who have never ploughed it. It requires the plough to be kept very sharp, and for this purpose the ploughman is always provided with a large file with which he keeps a keen edge as possible upon the share and coulter.

Such a team ploughs from one to two acres a day, usually about four inches deep, which is not near down to the bottom of the roots, so that the sod turned up affords but a scanty covering for grain that is sowed upon it at first, yet, very fine crops of wheat are raised in this way. It is also a common practice to break up in the spring and drop corn in every second or third furrow, and from which twenty or thirty bushels to the acre are often gathered, nothing having ever been done to it after planting. It takes two or three years for these sods to become thoroughly decomposed, and then the soil is of a light, loose, black vegetable mould, very easily stirred by the plough, but of a nature that it adheres to the plough in a troublesome manner. In fact, no plough has ever been found to keep itself clear; and the ploughman is generally obliged to carry with him a small wooden paddle, with which to clear off the adhering mass of dirt upon the mould board. With this exception, the prairie soil is generally one of the easiest in the world to till, and of course remarkably fertile.

By far the greatest portion is based upon a subsoil of clay, though in many places the subsoil is sand or gravel, and there are large tracts of which the surface is of this material. The streams are often broad and nearly covered with vegetable growth, in some instances to that degree that sheets of water many rods wide actually burn over during the autumnal fires.

Notwithstanding the many "interesting accounts of burning prairies," the fire upon a dry prairie in a calm time does not blaze as high as it would in an old stubble field. But in the marshes or wet prairies, it sometimes rages with most magnificent grandeur.

MARLING IN SOUTH CAROLINA.

Extracts from an Address to the Pee Dee Agricultural Society, by Dr. M. McLean.

There is another source of fertilization accessible to the planters, on and near the Pee Dee, which I can now only name. I mean the limestone and marl which are found in quantities inexhaustible on the very banks of the river. The subject is almost new to many of us, and one in which we are deeply interested. If time allowed I would dwell at some length upon it. Those who wish information in regard to it, are referred to the Farmers' Register, and the valuable Essay on Calcareous Manures, by the able editor of that excellent periodical; a work which ought to be in the hands of every member of this society, and every planter on the river.

Before closing I shall state an experiment made last season with the Pee Dee marl, by a Mr. Cunningham of Marion, on whose land a bed of it is found. It was spread at the rate of 200 bushels to the acre, on part of an old field of sandy soil, which had once been exhausted, and then suffered to lie out till it became covered with a growth of young pines. The marl was applied the second year after the land had been recleared, and the crop planted was Indian corn. Upon measuring the crop after it was gathered, the yield was found to be exactly double that of adjoining land of the same quality, planted at the same time and cultivated in the same way. This information I received from a gentleman of intelligence and respectability, who saw the crop growing, and saw the corn measured when it was gathered. Not knowing that I should use the information in this way, it did not occur to me to inquire what was the yield to the acre; but my informant stated that the growth was very luxuriant, that the number of stalks in the hill was two; that the corn succored freely, and that on some hills he counted as many as seven good ears, some of them on succors.

Lime can be delivered on the banks of the river, not far from Marr's bluff, at one dollar per barrel; and at a less price, if the purchasers furnish boxes in which to receive it. Marl can be shoveled from the bank into flats or boats lying in the river; and according to the best information which I have been able to collect, it may be delivered on the river bank at this place, at a price not exceeding 5 cents per bushel. Now, supposing 200 bushels of marl per acre, to double the planters crop, without increasing his labor of cultivation, whether, in that case, it would be a profitable operation for him to purchase it at that price, haul it to his plantation and spread it out, is a matter of calculation which every one may make for himself, in his own circumstances. The fertility imparted to soil by lime is more durable than that imparted by perhaps any other manure. The effect of its application to lands in Virginia, 50 and 60 years ago, are yet manifest, by the superiority of the crops produced by these lands, compared with those produced by adjoining lands. Lime seems to effect a permanent amelioration in the texture and qualities of the soil.

NO GUESSING—CUTTING OF HAY.

From the New England Farmer.

Mr. Editor—Much has been said and written upon the advantages of cutting fodder for cattle. I have frequently heard it said that to cut the feed for cattle, was a saving in the amount eaten of from 20 to 30 pounds to the hundred. An assertion to this amount, I not very long since read in your valuable paper. It appears to me some men *live for the sake of farming*, while others farm for the *sake of a living*. I get my bread by the sweat of my face, and have long since learned to receive cautiously the views of those who give experiments to the public from what "*my man*" says. I never was persuaded to be at the expense of cutting fodder for my stock, until the past winter. In the early part of last winter I purchased one of Green's machines for cutting straw and hay. After having learned my cattle to eat cut feed, (for I was obliged to learn them,) I commenced what I considered an experiment that would prove the loss or gain of cutting fodder. I weighed, cut and fed myself, with the exception of three or four days, when ill health prevented. And now if you think my experiment will be of use to my brother farmers, you may give it a place in the N. E. Farmer.

In 1840 I was unfortunate, and nearly lost my grass seed by the drought, so that in 1841, my crop was full half sorrel mixed with clover. Upon this hay I fed my cows, with the addition of now and then a foddering of corn stover. I commenced with two cows, the 29th of January, giving them all they would eat for seven days; at the end of which I found I had given them 270 lbs. All that remained of what I had given them, and which they refused to eat, was 3 lbs. Actually consumed, 267 lbs.

I then fed without cutting for seven days. At the expiration of this time, I found I had given them 290 lbs.; and there remained of what they refused to eat, 30 lbs. Actually consumed, 260 lbs.

I then put two cows more with those above referred to, and fed them on fine hay and herdsgrass for seven days, without cutting, and found there had been given them 491 lbs. There remained which they refused to eat, 45 lbs. Consumed, 446 lbs.

I then put them seven days on the same hay cut and mixed, and found I had given them 454 lbs. There remained of that which they refused to eat, 20 lbs. Consumed, 434 lbs.

It will be seen that in the last case, 37 lbs. more was given to the four cows of uncut hay, and 16 lbs. more was eaten than of that which was cut. This I account for in the change from the poorer to the better hay. Had the good hay been given first cut and then whole, the difference would have been the other way, in all probability; for the two weeks succeeding, they consumed a few pounds more of cut than of whole hay.

Perhaps you may suppose that by this time, my hay cutting machine is stowed safely away in some back corner, as lost and useless. But this is not the case. But I am thoroughly convinced that there is no saving in the quantity of hay by cutting. Nor do I believe that good clean hay pays the expense of cutting for any stock, unless it be for a horse. But coarse clover and coarse meadow hay pay well for cutting because cattle will eat *more* not *less*. I have cut and mixed these two kinds of hay, and if the condition of my cattle may be admitted as evidence of the benefit of cutting such hay, it is proved to my satisfaction. Yours, respectfully, OTIS BRIGHAM.

Westboro', 24th March, 1842.

☞ Mr. Brigham is worthy of all confidence. He has here given very valuable statements. The facts surprise us. We had supposed that there was more actual saving from cutting food for our cattle—but the statements of the scales must be taken;—a single tale from them is worth a thousand guesses. In one important respect this trial is deficient: the *time is not long enough*. To show that other trials have resulted differently, we copy the following statement:

"*Mr. Benjamin Hale's account of the saving made by the use of straw cutters, employed to cut hay and straw, as fodder for horses.*

Mr. Hale was proprietor of a line of stages running between Newburyport and Boston. He says:

	T.	*cwt.*	*qr.*	*lb.*	
The whole amount of hay purchased from April 1 to Oct. 1, 1816, (6 months,) and used at the stage stable, was - - - -	32	4	0	10	
At $25 per ton, (the lowest price at which hay was purchased in 1816,) -					$800 00
From Oct. 1, 1816, to April 1, 1817, whole amount of hay and straw purchased for, and consumed by the same number of horses, viz: - - - -					
Straw, *T.* 1 13 3 10					$160 23
Hay, 13 14 1 00					350 00
					$510 23
Deduct on hand April 1, 1817 by estimation four tons more than there was Oct. 1, 1816, at $25 per ton,					$100 00—410 23
Saving by the use of the					

straw cutter, four months of the last six months, or the difference in expese in feeding with cut fodder and that which is uncut, $389 77

Mr. Colman, if we are not mistaken, has somewhere given an experiment for three months, by which he made the saving 50 per cent. or more. —*Ed. N. E. Farm.*

ROLLING WHEAT IN THE SPRING.

From the New Genesee Farmer.

Mr. Colman—It is evident that much of the wheat through the country, especially on moist mucky lands, is injured by the frequent freezing and thawing during the past winter. Unless something can be done to remedy the evil, to some extent, we have to fear quite a failure in the coming crop.

Farmers may say that they have done all that they can do to secure a crop; but there is one thing which, if done in season, may effect a great saving. Let every farmer who has not one, provide himself with a good roller, and as soon as the season of freezing and thawing is over, roll his wheat fields thoroughly, and I have no doubt that it would save thousands of bushels of wheat in Western New York, the present season. Farmers! try it, leaving a part of a field unrolled, and give to the community the result of your experience at some future time. M. N.

Genesee Co., March, 1842.

Editoral Remarks.—Rolling and Harrowing Wheat.—The above advice is seasonable, and, we have no doubt, judicious. We should recommend something more than rolling; and that is, harrowing before rolling. As soon as the land is well dried, give your wheat fields a good harrowing, by passing over them with a horse harrow or one not too heavy; then roll them. In a fortnight or three weeks more go over them again with a harrow and a roller. Do not be afraid of destroying your wheat. Unless your harrowing is too heavy you will not displace or pull up many plants; and the advantages which those which remain will derive from the operation, will be a full compensation for any loss in this way. We have fully tested this matter more than once, having harrowed our wheat crops twice in a season, and after the plant was eight or ten inches in height; and with decided advantage, having left in such cases parts of the field untouched with a view to determine the expediency or inexpediency of the operation. The result has been highly beneficial. The effect of it is, by stirring the ground, to bring the air to the roots of the plant, and to loosen the soil so that they may extend themselves freely. This induces a vigorous vegetation, and causes the plant to tiller abundantly and throw out numerous shoots from the crown. We advise to harrow only in one direction. The rolling will serve to break the clods and to fix the plants, which are thrown up, in the ground. In England, wheat is frequently sown in drills with a machine adapted to the purpose; and afterwards cultivated by a cultivator, contrived to pass through and loosen the soil in the rows, as we plough and cultivate between the rows of our Indian corn. This is said always to be beneficial to the crop, though with our imperfect means such refined tillage can hardly be looked for, and, with prices of labor among us, might not be compensated.

We have yet to learn the value of constant tillage to the growing plant; and believe it would be found of the highest importance to our Indian corn to plough and cultivate it much more than we do. These suggestions coincide with the true philosophy of vegetation as far as it is understood, as such tillage causes a discharge of ammonia from the decaying vegetable matter in the soil, and quickens the receptive powers of the roots and leaves of the plant to take it in.—[Ed. N. G. F.]

ERRATA.—The article "On the different schemes of rotations," p. 175, was printed during the absence of the editor, which caused some typographical errors to appear, which otherwise would have been corrected. The only one, however, which affects the sense, is the word "*corn*," in line 23, col. 2, p. 176, which is a misprint for "come" in the manuscript. The reader will please mark the correction.

IRRIGATION.

From the Farmer's Encyclopædia.

In agriculture, the watering of the earth, to increase its productiveness. The term, however, is confined to that species of flooding which consists of spreading a sheet of water over a field or meadow, in such a manner that it can be easily withdrawn.

Irrigation, or the artificial watering of the earth, chiefly to produce increased crops of grass, has been in use from a very early period. In Oriental countries, in fact, the heat, of the climate is such, that, in many situations, the now productive soil would be absolutely sterile, were it not that the cultivator enriches his ground with a copious supply of water. The simile employed by Isaiah, (i. 30.), to indicate barenness and desolation, is "a garden that hath no water." And that, in patriarchal times, they labored hard to supply their grounds with water, by means of various hydraulic machines, some of which resembled the water-wheels of the fen districts of England, and were worked by the feet of men, something after the style of the modern tread-mill, is certain. Moses alluded to this practice when he reminded the Israelities of their sowing their corn in Egypt, and watering it with their feet (*Deut.* xi. 10; 2 *Kings* xix. 24,) and in the sandy soils of Arabia the same system is still continued (*Niebuhr*, vol. i. p. 121). According to Dr. Shaw, the following is the modern mode of raising and using the water of the Nile for the purpose of irrigation in Egypt: "Such vegetable productions as require more moisture than what is occasioned by the annual inundation of the Nile, are refreshed by water that is drawn at certain times out of the river, and lodged in large cisterns made for that purpose. The screw of Archimedes seems to have been the instrument formerly made use of for that purpose, through at present the inhabitants either supply themselves with various kinds of leathern buckets or else with a *sakiah*, as they call the Persian wheel, which is the most useful and generally employed machine. Engines and contrivances of both these kinds are placed all along the banks of the Nile, from the sea to the cataracts, their situations being higher, and consequently the difficulty of raising the water being greater, as we advance up the river. When their pulse, saffron, melons, sugar-cane, &c. (all of which are commonly planted in rills,) require to be refreshed, they take out a plug from the bottom of the cistern, and then the water gushing out is conducted from one rill to another by the gardener, who is always ready, as occasions requires, to stop and divert the current." In Egypt at the present day, according to Dr. Clarke, the water is sometimes raised, for the purposes of irrigation, by means of a wicker basket, lined with leather, which is held by cords between two men, who, by this laborious means, swing it over the banks of the Nile into the canal which conveys it to the lands intended to be irrigated. A machine similar to the Persian wheel is still employed in China by the cultivators, for the purposes of irrigation. This use of machinery for the purposes of watering might in fact, in many situations, be advantageously employed in England, to a much greater extent than is commonly believed. It is well known how many thousand acres of valuable land are profitably drained by means of the steam-engine. At this very period a public company is proposing to enclose and drain an arm of the sea in Lincolnshire, by the assistance of its gigantic aid. Yet how rarely, if ever, is that power employed to irrigate the thirsty lands of England; lands of all others the most profitable, the best adapted for the formation of water meadows? The tracts to which I allude are those on a slope, as on a side of a hill; but these are rarely found in situations where a sufficiently copious supply of water can be constantly obtained for the purposes of irrigation. Yet the quantity thus required is not so large as to be beyond the power of the steam-engine to supply; thus, to sufficiently saturate a square yard of a calcareous sand soil with water to the depth of one foot, as in irrigation, requires about 30 gallons of water, equal to about 145,000 gallons per imperial acre. Now, that the steam-engine could readily and profitably supply this quantity of water, may be concluded from several facts; thus, the two engines, one of eighty, the other of sixty horses' power, which keep Deeping Fen, near Spalding, completely drained, when working, in 1835, only ninety-six days, of twelve hours each, raised more than 14,000,000 *tons* of water several feet. The district drained by them contains about 25 000 acres (*Brit. Farm. Mag. N. S.* vol. iii. p. 300), which would otherwise be a complete swamp. And it has been proved that by a common condensing steam-engine, one bushel of coals would raise more than 50,000,000 lbs. of water one foot. In many situations, therefore, where, for the purposes of irrigation, good river water can be copiously obtained, and fuel is at a moderate price, I am confident that great results are yet to be obtained by the aid of mechanical power. For, by the steam-engine, the soils of all others the best adapted for irrigation may be successfully brought into cultivation; for instance, the poor sands and gravels on the sloping banks of many of the English and Scottish rivers, many of whose waters, from being charged with organic matter, the carbonate and sulphate of lime, and various earthy substances, are excellent for the use of water meadows. The early employment of irrigation by the Egyptians and Chinese was most likely the result of the good effects which were observed to be produced by the overflowings of the Nile and the Chinese rivers; for in the "Celestial Empire," irrigation has, it seems, been employed, according to their veracious historians, for a period long before that assigned to the flood. In Italy, especially on the banks of the Po, the cultivators of the earth have certainly employed this process for a period previous to the days of Virgil. (*Georg.* lib. i. v. 106-9)—

Deinde satis fluvium inducit, rivosque sequentes—

and it is still carried on with a zeal and care worthy of the art they practice. M. P. Cato, the earliest of the Roman writers upon agriculture, (150 years before Christ,) in his ninth chapter, told the Italian farmers to "make water meadows if you have water, and if you have no water, have dry meadows." The directions of Columella seem to have all the freshness of a modern age about them. He was the first who noticed the inferior nutrition afforded by the hay from water meadows. "Land," says he, "that is naturally rich, and is in good heart, does not need to have water set over it; and it is better hay which nature, of its own accord, produces in a juicy soil, than what water draws from a soil that is overflowed. This, however, is a necessary practice when the property of the soil requires it; and a meadow may be formed either upon a stiff or free soil, though poor when water may be set over it; neither a low field with hollows, nor a field broken with steep rising ground, is proper; the first, because it contains too long the water collected in the hollows; the last, because it makes the water run too quickly over it. A field, however, that has a moderate descent may be made a meadow, whether it be rich, or so situated as to be watered; but the best situation is where the surface is smooth, and the descent so gentle, as to prevent either showers, or the rivers that overflow it, remaining too long; and, on the other hand, to allow the water that comes over it quietly to glide off; therefore, if in any part of the field intended for a meadow, a pool of water should stand, it must be let off by drains, for the loss is equal either from too much water or too little grass." (*Col.* lib. ii. c. 16). Pliny tells us that "meadows ought to be watered immediately after the spring equinox, and the waters restrained whenever the grass shoots up into stalks" (*Nat. Hist.* lib. xviii. c. 27). When, after the fall of the Roman empire, agriculture, in common with all other sciences, rapidly declined, a very remarkable exception to this melancholy result of slavery and despotism was presented in the case of irrigation, which was carried on and extended through the long period of the dark ages with equal zeal and success. This was more especially the case in Lombardy, where it was certainly prosecuted on a very bold and profitable scale long before 1037. The princes of Lombardy patronized and followed the example of the various religious establishments, which then monopolized all the wealth and learning of the land, in extending the employment of water in all possible directions. The monks of Chiazevalle, in particular, were so celebrated for their knowledge of this branch of agriculture, and of hydraulics in general, that the emperor, Frederick the First, in the thirteenth century, very gladly sought their advice and assistance. This system has ever been zealously and carefully extended and improved, in every possible way. The waters of the chief rivers of the north of Italy, such as the Po, the Adige, the Tagliamento, and of all the minor streams, are employed in irrigation. There is no other country which possesses an extent of rich water meadows equal to that of the Lombards. The entire country from Venice to Turin may be said to be formed into one great water meadow; yet the irrigating system is not confined to grass lands; the water is conveyed into the hollows between the ridges in corn lands, into the low lands where rice is cultivated, and around the roots of vines. From Italy the practice extended into the south of France, into Spain, and then into Britain. In the states of Lombardy, the water of all the rivers belongs to the state; in those of Venice, the government extends its claims to that of the smaller springs, and even to collections of rain water, so highly, for the use of the cultivator, is water of every kind valued in the north of Italy. It is necessary, therefore, in Lombardy, to purchase from the state the water taken from the river; this may be taken, by means of a canal, through any person's grounds, the government merely requiring the payment of the value of the land to the proprietor, and restraining him from carrying his canal through a garden, or within a certain distance of a mansion. The water is sold by the government at a certain rate, which is regulated by the size of the sluice, and the time the run of water is used; this is either by the hour, half-hour, or quarter, or by so many days at certain periods of the year; the right to these runs of water is regularly sold like other property. Arthur Young gives an account of the sale of an hour's run of water through a sluice near Turin, which produced, in 1778, 1500 livres. The rent of the irrigated lands in the north of Italy is, upon an average, more than one-third greater than the same description of land not watered. (*Com. Board of Agr.* vol. vii. p. 189).

In Bengal, wells are dug in the highest part of their fields, and from this, by means of bullocks and a rope over a pulley, water is raised in buckets and conveyed in little channels to every part of the field. No attempts at cultivation are here made without the assistance of water, obtained by some mode or other.

The art of irrigation was not confined to the old world. The Mexicans practised it long before the days of Columbus; they collected the mountain torrents, and conducted their waters to their lands in proper channels, with much care and address. It was only towards the termination of the seventeenth century that water-meadows were constructed in Britain upon any thing like a regular system. Of these, those in Wiltshire, which are amongst the most celebrated in England, especially those in the Wylev Bourn, were made between 1700 and 1705. Those of Hampshire and Berkshire were constructed about the same period, but they were at first formed very inferior to the modern water-meadow lands of those counties. Great improvements were made towards the conclusion of the eighteenth century, through the publications of G. Boswell on meadow watering in 1780, and of the Rev. T. Wright, of Auld, in Northamptonshire, whose writings appeared at intervals from 1789 to 1810. It is noticeable that the water employed for these celebrated southern meads is perhaps the most clear and swift flowing of all the English rivers: issuing from the chalk formation, it is equally copious and transparent. Some of the chief advantages, therefore, of irrigation may evidently be derived from almost any description of water; for it is proved by the good effects produced by the brilliant chalk-waters of the south of England, and the still greater fertilizing effects of those surcharged with organic matter, as in the Craigintinny meadows near Edinburgh, that there is no water too bright or

too full of impurities, to be useless for the purposes of irrigation.

I propose in this paper to investigate the chemical properties of river water, and of the effects produced by it in irrigation, adding a few remarks upon the practice of the best and most skilful cultivators of the water-meadows of the south of England.

1. With regard to the composition of river water, there have been several chemical examinations; that of the Thames was analyzed by Dr. Bostock, who found, in 10,000 parts after most of its mechanically suspended matters had subsided, about $1\frac{3}{4}$ parts of foreign substances, viz.—

	Parts.
Organic matters	0.07
Carbonate of lime	1.53
Sulphate of lime	0.15
Muriate of soda	0.02

In an equal quantity of the waters of the Clyde, Dr. Thomson found $1\frac{1}{6}$ part of solid substances, namely,—

	Parts.
Common salt	0.369
Muriate of magnesia	0.305
Sulphate of soda	0.114
Carbonate of lime	0.394
Silica	0.118

The water of the Itchen in Hampshire is one of the most celebrated of all the southern streams, for the use of the irrigator. I found in 10,000 parts of its water, about $2\frac{1}{2}$ parts of solid matter, viz:—

	Parts.
Organic matter	0.02
Carbonate of lime	1.89
Sulphate of lime	0.72
Muriate of soda	0.01

From an examination of the substances found in these streams and they afford a pretty correct view of the contents of most others, the farmer will see that they all yield ingredients which are the food or natural constituents of the grasses. Thus, sulphate and carbonate of lime are found in most of them, and there is no river water which does not contain, in some proportion or other, organic matter. To ascertain, therefore, whether pure water was alone able to effect all the magic effects of irrigation, it was necessary to employ other water than that of rivers, lakes, or even springs. Pure water, as obtained by distillation, therefore, has been tried as a supporter of vegetation, but it was found totally inadequate to the support of plants,—they merely vegetated for a time, but they could not, by any means, be made to perfect their seeds. In this conclusion, the experiments of Dr. Thomson, and of MM. Saussure and Hassenfratz, entirely agree. Pure water, therefore, notwithstanding the dreams of the Greek philosophers, and the celebrated deceptive experiments of Van Helmont with his willow tree, is not able to support the growth of the grasses. Van Helmont's tree, when he planted it in an earthern pot, weighed five pounds; the earth previously dried in an oven, weighed 200 pounds; after five years it weighed 164 lbs., although it had been watered during that time with only rain and distilled water, and the earth had lost only two ounces in weight. Hence, said Van Helmont and his disciples, water is the sole food of plants. Bergman, in 1773, first pointed out the source of error. He showed, from the experiments of Margraff, that the rain-water contained a sufficient quantity of earth to account for the increased weight in the willow, every pint of rain-water containing one grain of earth. Then, again, the earthen vessel (which was sunk in the earth) would in this experiment transmit its moisture impregnated with all kinds of soluble substances. And yet, it has been shown, that impure water, such as that from a sewer or from a dunghill, is alone sufficient to sustain vegetation. This was clearly evidenced in the experiments of M. Lampadius; for he found, that plants placed in a pure earth, such as silica or alumina, although they would not grow when watered with pure water only, yet, when watered with the liquid drainage of a dunghill, they flourished very luxuriantly, and this fact has been also proved in another way. It has been shown by chemical analysis, that the quantity of solid or earthy matters absorbed by plants, is in exact proportion to the impurity of the water with which they are nourished. Thus, equal quantities of some plants of beans, fed by distilled water, yielded

	Parts.
Of solid matters or ashes	3.9
Those fed by rain-water	7.5
Those grown in garden mould	12.0

These facts strongly confirm the conclusions of some of the most sagacious cultivators, that the chief advantages of irrigations are attributable to the foreign substances with which the water is charged, although, as I have elsewhere observed, almost every farmer has a mode of accounting for the highly fertilizing effects of irrigation—one thinks it cools the land, another that it keeps the grass warm in winter. And this was Davy's opinion. He thought that a winter flooding protected the grass from the injurious effects of frost. He says, "Water is of greater specific gravity at 42 deg. that at 32 deg.—the freezing point; and hence, in a meadow irrigated in winter, the water immediately in contact with the grass is rarely below 40 deg., a degree of temperature not at all prejudicial to the living organs of plants. In 1804, in the month of March, I examined the temperature in a water meadow near Hungerford in Berkshire, by a very delicate thermometer. The temperature of the air at seven in the morning, was 43 deg. In general, those waters which breed the best fish are the best fitted for watering meadows, but most of the benefits of irrigation may be derived from any kind of water."

Such were the opinions of Davy as to the fertilizing properties of water. It is to be regretted that the opportunities for agricultural observations of this great chemical philosopher were so few, for his valuable remarks were always cautiously made. He appears, however, as I have remarked elsewhere, never to have steadily investigated the chemical composition of river-water with regard to its uses in irrigation, and, in conseqnence, knew little of the value of some of its impurities to vegetation. Thus, if the river water contains gypsum (sulphate of lime,) which it certainly does—if the water is hard, it must, under ordinary circumstances, on this account alone be highly fertilizing to meadows, since all grasses contain this salt in very sensible proportions; for, calculating that one part of sulphate of lime is contained in

every two thousand parts of river water, and that every square yard of dry meadow soil absorbs only eight gallons of water (and this is a very moderate allowance, for many soils will absorb three or four times that quantity,) then it will be found that, by every flooding, more than one hundred weight and a half of gypsum per acre is diffused through the soil in the water, a quantity equal to that generally adopted by those who spread gypsum on their clover crops, lucerne, and sainfoin, as a manure, either in the state of powder, or as it exists in ashes. And if we apply the same calculation to the organic substances ever more or less contained in flood waters, and allow only 20 parts of animal and vegetable remains to be present in a thousand parts of river water, then we shall find, taking the same data, that every soaking with such water will add to the meadow nearly two tons per acre of animal and vegetable matters, which, allowing in the case of water meadows, five floodings per annum, is equal to a yearly application of ten tons of organic matter.

The quantity of foreign substances present in river water, although commonly less, yet very often exceeds what I have thus calculated to exist in it. I have found it impossible, however, to give, from analysis, the amount which, under ordinary circumstances, is present in river waters, with any tolerable accuracy, since the proportion not only varies at different seasons of the year, but a considerable proportion of the merely mechanically suspended matters subside, when the specimen water is suffered to rest. In my conclusions with regard to the theory of irrigation, I have found many excellent practical farmers concur. Thus, Mr. Simmons of St. Croix, near Winchester, considers that the great benefit of winter flooding for meadows is derived, in the first place, from the deposits made by the muddy waters on the grass; and, secondly, from the winter covering with water preventing the ill effects to the grass of sudden transitions in the temperature of the atmosphere. This gentleman is perfectly aware of the value of the addition of the city drainage of Winchester to the fertilizing qualities of the Itchen river water, and of its superiority for irrigation after it has flowed past the city, having water meadows both above and below the town; and he finds that if the water has been once used for irrigation, that then its fertilizing properties are so materially reduced, that it is of little value for again passing over the meadows; and so convinced is he of this fact by long experience, that, having in this way long enjoyed the exclusive and valuable use of a branch of the waters of the Itchen for some grass land, a neighbor higher up the stream followed his example, constructing some water-meadows, and using the water before it arrived at those of my informant, who, in consequence, found the water so deteriorated in quality (though not sensibly diminished in quantity), that he had once thought of disputing the right with his more upland neighbor. The experience of other irrigators tends to the same conclusion. In the best managed water meadows of Hampshire the farmer does not procure annually more than three crops of grass; yet in situations where a richer water is employed, as near Edinburgh, four or five are readily obtained. It is evident, therefore, that the chemical properties of water have a much greater influence in irrigation than is commonly believed. The quality of the water, therefore, employed for the purposes of irrigation, is of the first importance to be well understood by the farmer; and although many more modern discussions have taken place upon the subject, yet the definition which the great Lord Bacon gave in his Natural History, of the advantages of "Meadow Watering," has never been excelled--"that it acts not only by supplying useful moisture to the grass, but likewise by carrying nourishment dissolved in the water." This nourishment is, generally speaking, composed almost entirely of the animal and vegetable matters mechanically suspended or chemically dissolved in the water; the fouler the water the more fertilizing are its effects. The objection which has been sometimes urged to this explanation, by instancing the prejudicial effects of some very thick muddy waters (as those of the Humber) on meadow lands, is very erroneous; for, in those cases, the mud deposited on the grass did not consist of animal or vegetable matters, but of fine earthy particles, such as clay or chalk, substances of which the alluvial soil, on which the same flood waters had for ages occasionally deposited their earths, was in fact entirely composed, and to which, in consequence, any farther supply was almost useless, the earthy slime merely covering the grass with mud, without adding a single fertilizing ingredient not already abounding in the soil. If, however, the soil is naturally deficient in any of the earthy ingredients contained in the water, then even such flood waters are ever found most fertilizing.

"The agency of water in the process of vegetation," says Mr. Stephens, "has not till of late been distinctly perceived. Dr. Hales has shown that, in the summer months, a sunflower, weighing three pounds avoirdupois, and regularly watered every day, passed through it or perspired twenty-two ounces each day, that is, half its weight. Dr. Woodward found that, in the space of seventy-seven days, a plant of common spearmint increased seventeen grains in weight, and yet had no other food than pure rain water; but then he found that it increased more in weight when it lived in spring water, and still more when its food was Thames water." (Practical Irrigator, p. 2.) And when speaking of the fact, that some irrigators think clear spring water equal to any, he adds (p. 24), "I would recommend to those who are of the same opinion, to inspect the irrigated meadows which are watered by the washings of the city of Edinburgh, where, I trust, they will find the superiority of muddy water to that of clear spring water most strikingly manifested."

Edinburgh has many advantages over the most of her sister cities; the large supply of excellent spring water is one of the greatest blessings to her numerous inhabitants, both in respect to household purposes and keeping the streets clean, as well as irrigating the extensive meadows situated below the town, by the rich stuff which it carries along in a state of semi-solution, where the art of man, with the common sewer water, has made sand hillocks produce riches far superior to anything of the kind in the kingdom, or in any other country.

By this water, about two hundred acres of grass land, for the most part laid into catch-work meadows, are irrigated; whereof one hundred and thirty belong to W. H. Miller, Esq., of Craigin-

tinny, and the remainder, to the Earls of Haddington and Moray, and other proprietors. The meadows belonging to these noblemen, and part of the Craigintinny meadows, or what is called the old meadows, containing about fifty acres, have been irrigated for nearly a century. They are by far the most valuable, on account of the long and continual accumulation of the rich sediment left by the water; indeed the water is so very rich, that the tenants of the meadows lying nearest the town have found it advisable to carry the common sewer water through deep ponds, into which the water deposits part of the superfluous manure before it runs over the ground. Although the formation of these meadows is irregular, and the management very imperfect, the effects of the water are astonishing; they produce crops of grass not to be equalled, being cut from four to six times a year, and the grass given green to milch cows.

The grass is let every year by public sale, in small patches of a quarter of an acre and upwards, and generally brings from 24*l.* to 30*l.* per acre per annum. In 1826, part of the Earl of Moray's meadow fetched 57*l.* per acre per annum.

About forty acres of the Craigintinny lands were formed into catch-work water meadow before the year 1800, which comprises what is called Fillieside Bank old meadows, and is generally let at from 20*l.* to 30*l.* per acre per annum. In the spring of 1821, thirty acres of waste land, called the Freegate Whins, and ten acres of poor sandy soil, were levelled and formed into irrigated meadow, at an expense of 1000*l.* The pasture of the Freegate Whins was let, previously to this improvement, for 40*l.* per annum, and the ten acres for 60*l.* They now bring from 15*l.* to 20*l.* per acre per annum, but may be much improved by judiciously laying out 200*l.* more in better levelling that part next the sea, and carrying a larger supply of water to it, which might be easily done without prejudice to the other meadows.

This, perhaps, is one of the most beneficial agricultural improvements ever undertaken; for the whole of the Freegate Whins is composed of nothing but sand, deposited from time to time by the action of the waves of the sea. Never was 1000*l.* more happily spent in agriculture; it not only required a common sewer to bring about this great change, but a resolution in the proprietor to launch out his capital on an experiment upon a soil of such a nature.

Since the making of the Freegate Whins into water meadows, Mr. Miller has levelled and formed forty acres more of his arable land into irrigated meadow, worth, before the formation, 9*l.* per acre per annum. It will only require a few years before these meadows will be as productive as the former; for it is evident that the longer water is suffered to run over the surface of grass land the greater quantity of fertilizing substance will be collected; therefore, as the water is so very superior in quality to all other water, a speedy return for the capital laid out may be expected. The expense of keeping these meadows in repair is from 10*s.* to 15*s.* per acre per annum, which is more than double the expense of keeping water meadows in repair in general.

It by no means, however, follows, as a necessary result of any contemplated improvement in irrigation, that the water should previously undergo a chemical examination. There are many other modes by which the farmer can form a pretty correct conclusion as to the fertilizing properties of the water he proposes to employ.

The surest proofs, says Mr. Exter, of the good quality of water (and the observations of this gentleman will be readily confirmed by the irrigators of the southern counties,) as a manure, are the verdure of the margin of its streams, and the growth of strong cresses in the stream itself; and wherever these appearances are found, though the water be perfectly transparent, the occupier of the soil through which it flows may depend, in general, of having a treasure, if he is attentive to it; but that this is not invariably the case, and that there are instances where a good water will not improve the herbage of certain soils, is proved by the following account (and there are several other cases with which I am acquainted) of the meadows of Mr. Orchard, of Stoke Abbey, Devon. These two meadows are situated on the side of a hill, their aspect nearly south—the superstratum a fine rich loam, from eight to ten inches deep, on a substratum of strong yellow clay. No difference whatever can be seen by the naked eye, in either the upper mould or the substratum, or in the herbage growing on the surface of them; except that, in the lower part of one, a few rushes appear, in consequence of some small springs which rise near them, but the water from them is not sufficient to render any part of the land poachy. At the head of the two meadows is a large pond, formed by the collecting of some small runs of spring water rising near it, and which is also improved by the wash of a small farm-yard adjoining, which, of course, must add to its efficacy as a manure. When this water is thrown over one of the meadows, it produces the richest herbage in abundance, and this field is regularly mowed for hay; on the other meadow, though repeatedly tried, it produces no good whatever. (Ann. of Agr. vol. xxx. p. 206.)

This result is attributable to the superior tenacious, retentive quality of the substratum of the lower field, or of some chemical difference in the composition of the soil; and although almost any description of soil is adapted to the formation of water meadows, those of a heavy clay description are generally the most unsuitable, those of a light or peaty kind are better, and those with a sandy or very absorbent gravel substratum still more so. There are some of the most celebrated water meadows on the banks of the Kennet of this description, and many of the best on the banks of the Wiltshire Avon have a mass of broken, porous flints for a subsoil. Those near Edinburgh, irrigated by the city drainage, rest upon the sands thrown up by the sea.

It is evident, therefore, that it is as important an object in the construction of these meadows to secure a ready and rapid exit for the flood-waters, as to procure, in the first instance, a copious and fertilizing supply.

The farmer is generally well aware of the injurious effects to his meadows of suffering the water to remain too long on them. He watches, therefore, with much care, for the first indications of fermentation having commenced, which is evinced by the rising of a mass of scum to the surface of the water—putrefaction is now beginning in the turf, and he knows very well that if the water is not speedily removed, that his grass will be either

materially injured, or entirely destroyed; he hastens, therefore, to open his water-courses. There are some soils in the vicinity of Standen in Berkshire, however, of so porous a quality, they need not any drains to empty the water-courses; and, in fact, in many instances, the farmer does not even require them: after a few hours all the water is absorbed by the soil; and yet these lands, with hardly six inches of mould above the gravel, are amongst the richest of water-meadows; the roots of the grasses penetrate readily into the gravel, and the earliest and sweetest grasses are produced on them.

Almost any description of grass will flourish under proper management in water meadows. Those whose soils consist of peat resting on sand or on sandy loam, with a substratum of chalk or gravel, generally produce the meadow foxtail (*Alopecurus pratensis,*) the brome-grass (*Bromus arvensis,*) and the meadow-fescue (*Festuca pratensis,*) on the tops and sides of the ridges. The furrows and sides of the drains are usually tenanted by the creeping-bent, the hard fescue, the rough stalked meadow grass, and the woolly soft grass. In those water meadows, whose soil consists of a sandy loam on a clay subsoil, the chief grasses are commonly the creeping-rooted soft grass, crested dog's-tail, the meadow barley, and the sweet-scented vernal grass. But some grasses change their appearance in a very remarkable degree, when exposed under favorable circumstances to the influence of the flood waters. This fact is strikingly exemplified in the case of two small meadows situated at Orcheston, six miles from Amesbury in Wiltshire, denominated from their great produce, "the long grass meads." "These," says Davis, "contain together only two acres and a half, and the crop they produce is so immense, that the tithe hay of them was once sold for five guineas." Much discussion took place amongst the Wiltshire farmers, as to the nature of the crop of these meads, before it was at last shown that the greatest part of their herbage consisted of nothing else than the black-couch, or couchy-bent, the *Agrostis stolonifera*, one of the worst of the grasses or weeds which haunt the poor, ill-cultivated arable soils.

It is a very general, as well as correct conclusion of the English farmers, that the grass and hay of water-meadows is not so nutritious as that of the permanent pasture lands. The difference, however, is not so great as is commonly supposed. The late Mr. George Sinclair determinated this experimentally, and he is no mean authority with regard to all that relates to the grasses.

He obtained from the rye grass (*Lolium perenne,*) at the time of flowering, taken from a water meadow that had been fed off with sheep till the end of April, of nutritive matter, seventy-two grains; and from the same weight of this grass, taken from a rich old pasture, which had been shut up for hay about the same time, ninety-two grains. From the same grass from the meadow, that had not been depastured in the spring, one hundred grains. And from the same grass, from the pasture which had not been fed off, one hundred and twenty grains. All the grasses, in fact, where their growth is forced by the application of either liquid or solid manures, are found to contain nutritive matter in diminished quantities —this, too, was determined by Sinclair. From four ounces of a very rankly luxuriant patch of rye-grass, on which a large portion of cow dung had been deposited, he obtained of nutritive matter, seventy-two grains. From the same quantity of the same grass, growing on the soil which surrounded this luxuriant patch, he obtained one hundred and twenty-two grains.

And in a second trial, the same species of grass, on a soil entirely destitute of manure, afforded, of nutritive matter, ninety-five grains. On the same soil, excessively manured, the grass afforded only fifty grains. In these experiments, the plants were of the same age, and were examined at the same stage of their growth. (Hortus Gram. 384.)

With regard to the construction and management of water meadows, there are many practical works of the highest authority to which the farmer has ready access, and, in the following observations, therefore, I shall merely very briefly paraphrase the accounts given by Mr. Davis and others, of the practice of irrigation in the southern counties. In this, however, even since the time that Davis wrote, there has been a great and steady improvement. The land is better levelled, the slopes more evenly preserved, the water-way, aqueducts, and hatches, better constructed, and in many of the more recent improvements in the valley of the Itchen in Hampshire, the sliding-water doors are regulated by a cogged wheel turned with a moveable winch, so as to render them safe from alteration during the absence of the meadow-keeper.

The management of the Wiltshire and Hampshire water-meadows, as well as it can be briefly described, is as follows:—In the autumn, the after-grass is eaten off quite bare, when the manager of the mead (provincially the drowner) begins to clean out the main drain, and the main carriage, and to "right up the works," that is, to make good all the carriages and drains which the cattle have trodden in, so as to have one tier or pitch of work ready for drowning. This is immediately put under water, whilst the drowner is preparing the next pitch.

In the flowing meadows this work ought to be done, if possible, early enough in the autumn to have the whole meadow ready to catch the first floods after Michaelmas; the water, being the first washing of the arable land on the sides of the chalk hills, as well as the dirt from roads, is then thick and good; and this remark as to the superior richness of the flood waters, is one that is commonly made in Berkshire and other parts of England. The length of the autumnal watering cannot be precisely stated, as much depends upon situations and circumstances; but if water can be commanded in abundance, the custom is to give meadows a "thorough good soaking at first," perhaps for a fortnight or three weeks, with an intermission of two or three days during that period: and continue for the space of two fortnights, allowing an interval of a week between them. The works are then made as dry as possible, to encourage the growth of the grass. This first soaking is to make the land sink and pitch close together, a circumstance of great consequence, not only to the quantity, but to the quality of the grass, and particularly to encourage the shooting of new roots, which the grass is continually forming, to support the forced growth above.

While the grass grows freely, a fresh watering is not wanted: but as soon as it flags, the water must be repeated for a few days at a time, always keeping this fundamental rule in view, "to make the meadows as dry as possible after every watering, and to take off the water the moment any scum appears upon the land, which shows that it has already had water enough."

Some meadows that require the water for three weeks in October, and the two following months, will not, perhaps, bear it one week in February or March, and sometimes scarcely two days in April and May.

In the catch-meadows, which are watered by springs, the great object is, to keep the works very dry between the intervals of watering; and as such situations are seldom affected by floods, and generally have too little water, it is necessary to make the most of the water, by catching and rousing it as often as possible; and as the upper works of every pitch will be liable to get more water than those lower down, a longer time should be given to the latter, so as to make them as equal as possible. (Davis' Agriculture of Wiltshire, p. 125-7.)

In Berkshire they first flood their water-meadows about Michaelmas; these are situated principally on the banks of the Kennet. The first flooding they deem the richest in quality: this they keep on the land for about four days, then they dry them for about a fortnight, and after that the water is let on for three or four days more; those meadows which are the most readily dried are the most productive. There are none more so, in fact, than those which have a porous, gravelly, or broken flint bottom, from which the flood-water readily escapes, almost without drains. They begin to feed their meadows with sheep about the 6th of April, and continue feeding till about the 21st of May, when the meadows are again flooded for a crop of hay; the land is then flooded and dried alternately for three days until hay-time.

The number of acres of land in Wiltshire under this kind of management has been computed, and with a tolerable degree of accuracy, to be between fifteen and twenty thousand. Some considerable additions, however, have been made to the water-meadows of the district since this calculation was made. (Davis' Wilts., p. 122.) About the same number of acres are formed into water meadows in Berkshire, and a still larger number in Hampshire. No one has attended more carefully to his water meadows than Lord Western, on some of those situated on the London clay formation in the Blackwater Valley in Essex, a soil of all others, perhaps, from its tenacity, the least adapted to their successful formation, and his testimony is very important—"There is an old adage," says his lordship, "that water is the best servant in agriculture, and the worst master. Water has in itself intrinsic value, distilled through chalk, lime, or marl, it acquires a portion of their qualities, though preserving the most perfect transparency, and, coming down in torrents and floods, it carries along the finer particles of earth and manure from the mountains, or higher grounds, into the valleys; hence, of course, it is that the valleys derive their fertility, and the value of the meadow has been originally created by an accumulation of wealth from the hills." (On the Improvement of Grass-lands, pp. 5, 14, 23.)

"In descending the Jura mountains, which divide France from Switzerland, the very first pasture you find on the descent evinces the value placed on the mountain floods by the inhabitants of those districts; and, accordingly, every stream is sedulously directed and conducted over the pastures in a most skilful manner. The very washing of the roads in hasty rains is also attended to, and applied to the same purposes." This system of catching the uncertain flood-waters is known amongst farmers by the name of catch-work, and though highly valuable, yet they deem it infinitely less important to them than irrigation, which is watering (generally five or six times a-year) from a certain and ever-accessible head of water, as a river, &c. And yet Lord Western's test mony is decisive in favor of even one catch-flooding; for he observes, when speaking of the expense of constructing the requisite little channels to disperse the flood-waters over the grass—"In many cases it will be trifling, in some cases considerable; but when the farmer reflects that one winter's flooding will do more in many, I may say in most cases, than thirty loads an acre of the best rotten dung manure that can be laid upon his grass lands, he can hardly shrink from some considerable expenditure." If, then, the effects even of a catch-flooding with water are so great, how infinitely superior are the advantages capable of being derived from a regular constant supply of the enriching foul waters, like those issuing from the drains of a large city, which is even now most successfully employed near Edinburgh, but worse than wasted in the case of London. Whatever may be the value, in an agricultural point of view, of the solid contents of the London sewers, yet, to me, the absolutely liquid portion, for the purposes of irrigation, appear at least equally important.

There is no agricultural question, therefore, of more consequence in a national point of view, than that of the improvement of the soil by the practice of irrigation; for, in its prosecution, all the rich organic and other matters diffused through the rivers, which would otherwise be carried into the sea, are saved to agriculture. This is not, therefore a question like that attending most other modes of fertilizing the soil, merely transposing manure from one field or district to another: but it is the absolute recovery, as it were, from the ocean, of a mass of finely divided enriching substances, constantly draining from the land. It is the effectual diversion of a stream which is ever steadily impoverishing all cultivated soils, and which unnoticed, and in too many instances deemed worthless, gliding into the ocean, is almost the only drawback to the steadily increasing fertility of our country.

GYPSUM.

From the Genesee Farmer.

Josiah Bordwell, of South Hadley, Mass., has four acres of pasture ground, and applies to it annually one thousand pounds of gypsum. The same application, and at the same rate, has been made 35 years in succession. On this lot he pastures annually one large yoke of oxen, one horse, two cows, and some years three cows. Prior to the use of plaster, Mr. B. says it required at least

six acres of this land to afford as much feed as he has obtained from one acre, by using plaster.

He has also a piece of mowing ground which contains four acres. Two crops of hay are taken from it regularly. On this ground he uses plaster of Paris freely, and applies a top-dressing of manure. His annual product of hay is fully sixteen tons.

For the Farmers' Register.

ADDRESS ON THE FORMATION OF THE AGRICULTURAL SOCIETY OF ESSEX.

At a meeting of the farmers and planters of Essex, convened at Tappahannock, on the 28th March, 1842, for the purpose of forming an Agricultural Society, the following address was delivered by their countryman,

JAMES M. GARNETT.

Friends and brother farmers:—Few things have happened to me, for a long time past, which have gratified me more, than to find so many of you desirous to establish an agricultural society, and to be the individual invited by yourselves, to address you on the occasion. To be thus honored is, of itself, a circumstance which, I confess, has given me much pleasure. But I assure you with perfect sincerity, that my highest gratification arises from the reflection, that although our good old county has done many good things in her day, none I believe has ever rendered her so much real, substantial service, as she will almost certainly derive from the association which I earnestly hope you have all come prepared to establish. In every part of our own country where similar societies have been formed, and well managed, their good effects have soon become manifest to the most careless observer; and the experience of all foreign countries has borne ample testimony to the same facts. Still, we Virginians have not appeared generally well disposed to avail ourselves of these associations, however strong and conclusive their benefits appear, to all who will give them an attentive consideration. In fact, the members of our class every where, but especially in our own state, have always appeared to me less inclined than any others to combine into societies, and co-operate for their mutual benefit; and yet, none surely require it more. For our legislatures have always acted towards us, as if we alone could never be in need of that aid, which has scarcely ever been sought from them by any other class without being granted. Hence the greater necessity of striving by co-operation to help ourselves if we will persist in neglecting to use the means—always in our power—of obtaining legislative aid. These means are as perfectly simple, as they would be efficacious. We have only to substitute *real* instead of *pretended* friends for our legislators, and the work would be speedily accomplished. But in the absence of all effective legislation in our favor, and whilst we fail to seek it as we might, there are no means which appear to me so well calculated to supply the want of it as agricultural societies. They greatly accelerate the acquisition of that knowledge of our profession which is but slowly gained by solitary study and practice, even where we are really zealous in the pursuit of it. They furnish a cure for that self-conceit, so highly injurious to such of our brethren, as believe themselves too wise to be taught; by placing them in a situation to be convinced—where the disease has not gone too far to be cured—that others know more than they do. They serve to excite that "*esprit du corps*," which causes us to take a just pride in our profession, and in which our class is so deficient. They draw closer those bonds of fraternity which should always unite us indissolubly together. They greatly promote social intercourse; and thereby tend powerfully to mitigate, if not entirely to cure those animosities and bitter hatreds, with which party-spirit never fails to poison the hearts of all who give themselves up to its influence. In a word, agricultural societies are, so far as my experience enables me to judge, the sources of unalloyed good to all who become zealous members thereof. And who can doubt it, that will reflect but for a moment on the nature and all pervading influence of that great cause, which it is the special object of agricultural societies to promote. A celebrated German agriculturist, whose late work on "Organic Chemistry in its application to Agriculture and Physiology" has become one of the text books in agricultural science, has summed up in a single sentence the chief circumstances which render this cause so great, and of such vital interest to all mankind. His words are, "There is no profession which can be compared in importance with that of agriculture; for to *it* belongs the production of food for man and animals; on it depends the welfare and developement of the whole human species, the riches of states, and all commerce." This single sentence contains what might be expanded into volumes of illustration and praise; but I confidently trust that all of my brother farmers who now hear me are sufficiently apprized of the essentiality of our profession to all the best interests of our country, not to require such a diffuse eulogium to recommend it farther to our special regard.

If it were my sole object to endeavor to make you fall in love with your profession, I might paint for your imaginations only the pleasures of agriculture, the green meadows, the verdant lawns, and glowing landscapes of well cultivated, highly productive fields, with which an all bounteous Providence hath enabled the cultivators of the soil to solace and regale both their animal and intellectual natures. Such an attempt would be both easy and delightful. But on the present occasion, I feel myself called on not only to exhibit some of the most striking advantages of agriculture to individuals and communities, together with the most practical means of improving it, but also to trace a warning chart of the shoals and quicksands, the rocks and barren wastes, that too frequently impede the progress of the husbandman, exhaust his substance, and mar his happiness. This, although the most necessary, is by far the most irksome part of the duty, which I shall now attempt to perform. In my endeavor to execute it properly, should I be so fortunate as to suggest any hints which may prove practically useful, I shall deem myself amply rewarded.

In regard to the general advantages of agriculture, both to individuals and nations, no one probably is so ignorant as to require much to be said

to him in the way of explanation. There are none, for instance, but must know, that the yeomanry of a country constitute the pay-all-class; that they furnish the means of subsistence, both in peace and war, to all other classes; that all taxes for the support of government, or any other public exigency, must ultimately come out of the land, and be drawn from it by the labor, skill and industry of those who own and cultivate it. How vastly important then, how absolutely necessary is it, that they should possess all the knowledge of their profession, both scientific and practical, which it is possible for them to acquire, since not only their own welfare, but that of every other class—nay, of the community itself of which they are members, vitally depends upon the extent of this knowledge, and the persevering diligence with which it is applied to all the various branches of husbandry. Yet, most strange to say, ours is a profession which multitudes of us appear to think may be practised successfully, as it were by instinct, for many, very many take it up without the slightest previous study or experience, and take it in high dudgeon, even if the oldest farmers venture to question their qualifications. What renders this misconception the more surprising is, that it is never made in regard to the simplest of all trades and callings, that even cobblers and tinkers are required to serve some apprenticeship, before they undertake to act as master-workmen. But *our* farmers make no such preparation, no, not they; although theirs is a vocation, which if estimated by its national importance, and the great variety of knowledge essential to the attainment of excellence therein, must certainly rank among the highest in society.

As to the means of our improvement in husbandry, although some small capital in money, or its equivalent, is generally deemed necessary to begin with, a capital in agricultural knowledge, sobriety, honesty, industry, and economy, is still more essential; for without these, and a good stock of them too, it is folly for any man to expect to reach a high standing in his class. To do this, he must carefully shun all extravagance, he must be just and fair in all his dealings, indefatigably diligent in all his farming operations, giving to each its due share of attention; perfectly sober in his habits, that he may be always fit for business as well as an example of sobriety to all under his command; and to crown the whole he must neglect no means within his reach to improve himself, both in the knowledge and practice of his profession. One of the most obvious of these means, especially for those who have no access to agricultural books, nor time to study them, is to become a member of some well managed agricultural society. All of these associations meet once or twice a year; and thus furnish opportunities for each member to learn, if he pleases, all that may be known by the rest, within the limits of their particular society. Here, then, any individual member who seeks information may acquire, in a day or two, more knowledge of his profession than he would probably gain in some years, by relying entirely on his own practice at home, unaided either by books, or conversation with farmers more experienced than himself. Moreover, his attendance on these meetings would be apt to inspire him with a more humble sense of his own agricultural knowledge, than most of us are apt to have who mix so little with our brethren as to have no opportunity of comparing our own acquirements with theirs. The neglect to do this is almost as sure to infect our minds with an overweening notion of our own knowledge, as the neglect to till our fields is, to fill them with noxious and pestiferous weeds. In fact, without a considerable degree of humility, there can be no desire to learn, for there is no consciousness of deficiency, no belief hardly in the possibility that others know more than we ourselves do.

Another advantage in attending the meetings of an agricultural society is, that we are apt to feel a livelier interest in our vocation; and to take a more enlarged view of its national importance, than we would ever possess, if we wilfully neglected, as too many of our brethren are apt to do, to look a little beyond our own thoughts for the means of improvement. To effect this most rapidly for our minds, frequent interchanges of opinion relative to every thing connected with our profession is quite as necessary, as the frequent application of fertilizing substances is to accomplish it for our lands. And he who neglects to avail himself of this all important fact, well deserves to live and die under the fatal curse of *that* ignorance, which self-conceit, and its constant companion, obstinacy, are sure to fix upon all who give themselves up to their influence. Most truly may it be said of any such man, "there is more hopes of a fool than of him."

I have said that one of the means of our improvement in husbandry is, to become an active member of some agricultural society. But much depends upon how this society is constituted, and how it is managed. To enable it to effect well the purposes for which it was established, all who become members should determine, and persevere in that determination, annually to do something more towards its support and improvement, than merely to pay punctually their subscription, although *this* should ever be deemed an indispensable duty. Each cultivator of the soil, however poor he might be, may certainly do this; for it does not require that a man should be rich to make and report accurate experiments on a small scale; and such experiments have often been known to result in the most important discoveries. In fact, some of those which have been most beneficial to mankind have been made by men comparatively poor. Again, members who are not cultivators, but belong to other professions and callings, may aid the cause very much, by always attending the meetings of their society, and exerting whatever influence they may possess to render it popular. We are all more or less creatures of imitation, and generally prone to do what we see others do. Of course, if many unite zealously in any pursuit, especially if it be one for the promotion of that greatest and most essential of all arts, the art of agriculture, others will assuredly follow, some merely for company sake, but numbers probably from the laudable motive of bearing a part in the general effort to do good.

Another means highly necessary to the beneficent operation of agricultural societies is, to establish and to cherish correct opinions, as to the nature and objects of the premiums which are usually offered by them. These are to excite a greater degree of fair, honorable competition, in

the various branches of husbandry than would probably arise without them; not, however, for the special benefit of the individuals who may engage in it, but more effectually to promote and improve the particular branch, wherein the competition is produced. This should always be borne in mind by the competitors, and they should always deem it highly dishonorable to become, what an old member of our Fredericksburg Agricultural Society has most aptly called "*prize fighters*," that is, men who compete for those premiums solely for the sake of the paltry gain, and who almost always withdraw, if disappointed in their sordid objects. If they do not take this step, which at once displays the baseness of their motives, they may always be known by the gross abuse which they never fail to utter against the committees that have decided against them. This is an evil to which all agricultural societies, that give premiums are constantly exposed; and there is none from which they should labor more to free themselves. But nothing, I believe, would do it, unless perhaps it were made a part of the constitution of every society to expel a member for accusing any committee of partiality, in fulfilling a duty which they can have no possible motive to abuse. On the contrary, they have every inducement which can operate upon men in such situations to discharge this duty faithfully, since they cannot possibly gain any thing by violating it. Possibly the disgrace of expulsion might deter these "prize-fighters" from indulging their ribaldry, when disappointed in obtaining a premium, although such a remedy is at least doubtful; for the men who would be most apt to offend in this way, have generally too little sense of honor and justice, to regard what a truly honorable man would consider a disgrace. The only thing which they really dread is either corporal or some other punishment that would take money out of their pockets. No agricultural society can ever derive the smallest benefit from them, and none should ever be admitted, if their characters could possibly be known beforehand.

I have said more, perhaps, on this subject, than some of you may think there was any necessity for saying. But if you form a society, as I sincerely hope you will, your members will be peculiarly fortunate, indeed, if they do not soon find among them some such disturbers of their peace and prosperity as I have described.

Let the foregoing remarks suffice to show how we may improve in our profession, by becoming members of some agricultural society. But this alone will be far, very far from making us good farmers and planters. We must not only learn all we can from our brother members, and be always ready to adopt their practices, whenever we see good reason to believe that they are better than our own, but we should dread, as we would poison, that pride and pertinacity of opinion which all our brethren are so apt to contract, who neither study their profession as a science, nor seek any other means to improve in its practice, than such as their own unaided thoughts may possibly suggest. This entire self-dependence for an increase of knowledge, soon swells into a degree of preposterous, arrogant self-conceit, which as effectually shuts the mind against the access of all truth, all improvement, as a good cork shuts a bottle from the admission of air. With hearts and intellects properly prepared for the acquisition of knowledge, by a proper distrust in our own acquirements, and a desire to increase them, both of which will be augmented by associating with men better informed than ourselves, we shall certainly be led to seek, not only *this* source of improvement in our profession, but we shall resort also to agricultural books.

Some of these, in the form of periodical papers, have now become so cheap, that every man who is not actually a pauper may easily furnish himself with at least one of them, as the cheapest costs only a dollar a year, although a single paper will often be found to be worth many dollars to him who will read it attentively. This remark I have very often heard, and from men too who were once silly enough to laugh at every thing in print, on the subject of husbandry, until they became thoroughly convinced of their own folly and obstinacy, in neglecting to ascertain for themselves, what agricultural books and papers really were. They then discovered that they were precisely the same with oral communications on the same subjects. The only difference being, that the first is the experience of farmers recorded *in print*, and the latter the experience, often of the same farmers, imparted *by word of mouth*. The facts, communicated in either way, must be exactly of the same value, as must also be all the speculations, either oral or printed, which may be blended with them; and stupid, indeed, beyond measure, must he be, who could not so distinguish between them, as to derive benefit from the facts, if worthy of regard, and avoid injury from the speculations, if they were either inconclusive or utterly visionary. This matter is now so generally and well understood, that the individual who ventures to sneer and scoff at what he is pleased to call "book-farming," will rarely fail to be thought a vain, conceited ignoramus, however he may escape being called so to his face. He can no longer thus disguise his own ignorance and aversion to learning, nor pass himself off, even among his most illiterate brethren, for a farmer of superior knowledge and skill in his profession; but must go for what he really is, an arrogant, opinionative boaster, utterly too lazy to study, too self-conceited to believe others better informed than himself, and far too proud to confess it, even if forced to see and to feel his own inferiority. I have said the more on this topic, because I verily believe that an overweening confidence in our own knowledge is the besetting sin of our class, owing to so few of us ever studying our profession as a science, to the solitary lives we generally lead, and to our consequent ignorance of the daily improvements which are constantly making in all the various branches of husbandry. Of these we must keep ourselves well informed, either by reading or frequent interchange of opinions, on all subjects connected with our profession, but both are best; or we must be content to suffer all the penalties and deprivations of our willful ignorance.

Another method of improving in our husbandry is one which few, very few pursue, although it really seems to me demonstrable that it would greatly contribute, not only to our knowledge, but to our wealth. It is, to lay out whatever clear profit, (if any,) which we can make from our

farms, in augmenting their fertility, rather than in adding to their size. Any man, who will take the trouble to make the calculation, may very soon convince himself of this fact, so highly important to all agricultural improvement. For instance, is it not perfectly plain, that if we increase our crops merely by increasing the surface cultivated, we must add a proportionate increase of labor and other means to make them, and of course have our expenditures and income relatively the same as before? We therefore gain no additional clear profit, although we gain not a little additional trouble in managing this increased labor. Yet almost every farmer, who has it in his power, continues to add negro to negro and acre to acre, whenever an opportunity offers; and thus not only fails to augment his own net income in the smallest degree, but actually contributes, by his perpetual buying up more and more land, without improving what he already owns, to depopulate the neighborhood in which he lives. In this way it has happened that in many parts of Virginia a single proprietor will now own many thousands of acres, which half a century ago, or within a shorter period, were divided into several distinct farms, each of which sufficed for the comfortable support of a different family, who might still have been living on them in abundance, if the money, time and labor, which it cost them to move and to form other far distant settlements, had been judiciously expended in improving the homes of their ancestors, and the lands which gave them birth. No man can doubt this, who knows, half as well as I do, how capable these lands are of being so improved as to yield even ten or twelve times their present average product. For it is a fact within my own knowledge, that many of our Virginia farms formerly produced per acre crops which exceeded what they now yield full as much as I have stated, whilst others which were almost barren, when I first knew them, having fallenin to the hands of improving proprietors, instead of the land-skinners who previously owned them, are now producing ten, fifteen, and even twenty-fold as much as they did in the hands of those deadly enemies to all agricultural improvement. It may be prejudice, but I confess I have always considered such men among the very worst members of society; for, although they increase for a time the means of human subsistence, it is solely for their own exclusive benefit, without the slightest regard for the general welfare or their own posterity; and under an absolute certainty of ultimately impoverishing their own state, by destroying the productiveness of her soil to the utmost extent of their power. To this deplorable situation they have reduced thousands upon thousands of acres of our once fertile soil. But with a knowledge of its capacity for improvement which most of its present owners possess, what should hinder them from restoring these lands to their former state, or to one still more productive, since many of them are now known to contain in their marl deposits the natural means of effecting this restoration? The only obstacle in regard to these farms is, either that sheer laziness in their proprietors, which causeth the sluggard to be continually saying to himself, "*yet a little sleep, a little slumber, a little folding of the hands to sleep,*" or else it is an inveterate habit of putting off from day to day what they wish and mean to do; a habit, by the way, which is utterly incompatible with every thing like good farming. Procrastination has been called "*the thief of time;*" but it is infinitely worse: it is the slow but deadly poisoner both of mental and bodily energy, rendering the best resolutions entirely abortive, and the greatest physical powers nearly as useless to us as if we did not possess them.

Our population, computed by the square mile, and compared with that of the northern and eastern states, falls very far short of theirs, although we have greatly the advantage of them both in soil and climate. Do any of you wish to know the reason? It is simply because *they* have been constantly and most industriously laboring to improve *their* lands, whilst we (with few exceptions) have been as constantly treating *ours* in a way that could not well have been worse, if we had actually been laboring with might and main to wear them out. I will not say that such was the design of our treatment; but the effect has certainly been the same as if malice prepense had instigated all our proceedings. No state pride, no attachment to the places of our nativity, no affection for kindred and friends, no devotion to agriculture, as the great source both of individual and national prosperity, has had any such influence over us, as to save our good old Mother Virginia from the almost hopeless impoverishment to which a vast portion of her soil has been reduced by the neglect, the abuse, and constantly exhausting culture of her improvident, reckless children. The deplorable consequence of this has been, that multitudes of them seem so disheartened by the prospect before them, as almost to have lost the power of making the necessary exertion to better their condition, although there are now very few neighborhoods, and no counties which do not afford some highly laudable examples demonstrative of what rapid improvement may be made of our exhausted soils, simply by persevering industry and labor, judiciously applied to the various processes by which worn out lands may be restored to a highly productive condition. There are no soils so poor as not to furnish to their owners more or less of such materials as may be easily converted into manure; for such are all substances that will rot. Moreover, a very large portion if not the greater part of our lands below the head of tide-water, abound with marl, that has never failed to restore land to fertility, wherever it has been judiciously applied. On farms destitute of marl, the numerous substances convertible into manure, aided by lime, plaster of Paris and red clover, will soon effect the object, and that too without any great outlay of cash, if we could only content ourselves with a small, gradual beginning. But our great misfortune is, that very few of us, even among those who have least property, have yet learned to practise upon the good old Scotch proverb—"*Many a little makes a mickle.*" Hence it happens with such persons, that because they cannot command money and labor enough to make, as it were, by a hop, skip, and jump, all the improvements they wish, they will not attempt to make any; but go on from bad to worse, until emigration presents itself as the only remedy for an evil which seems incurable, merely because no effort has been made to cure it. How long such num-

bers of our brethren will continue to labor under and to suffer from an infatuation so deplorable, so paralyzing, GOD only knows; but so long as they do, a man might as well preach to so many deaf adders, with the expectation of doing them any good. They seem infinitely to prefer lounging away their time at any place of public resort, where such dronish idlers as themselves are most apt to congregate. There, perhaps, they interchange very profound condolences about "the hard times," without the least apparent consciousness of their own participation in creating them; or, should a tippling shop be at hand, their favorite occupation generally is to settle the affairs of the nation therein, and ever and anon to wash down their patriotic effusions with copious libations of whisky and brandy to some political idol. In the mean while their farms are left in a great measure to take care of themselves, and to regain fertility, if that be possible, by almost total neglect. Happy for our country, and most happy for such persons themselves would it be, if by any means they could be cured of their self-destructive habits, and converted into industrious, frugal, persevering farmers. The whole appearance of our own state, as well as of many others, would soon be changed by it; we should cease to hear of any farm being deserted from its supposed incapacity to support its owners; and it would not be long before our good old Virginia would begin to look and to feel something like what she once was in her most prosperous days.

There is still another important change essential to our improvements in husbandry, which *all* of our farmers who have young sons are deeply concerned in making. It is, to abandon the preposterous practice of crowding nearly all of them into the professions of law and physic, instead of trying to make good farmers of them; than which there is no more honorable vocation, nor any one that has so many considerations to recommend it to our regard. Ask any man whom you please, if he does not feel certain that we have an overstock both of doctors and lawyers, and he will certainly answer *yes*. But still we are constantly adding to the number, as if there was really no other honest pursuit by which they could make a living. In the whole compass of supposition, there is (at least in my opinion) but one which will reconcile this practice to common sense; and I hardly think we shall find any gentleman of either profession willing to admit it to be true. It is, that to multiply lawyers and doctors is to increase sickness, diseases, and litigation. If adding to the former would diminish the number of the latter, as it certainly would, provided the doctors and lawyers were all masters of their profession, and strictly honest as well as conscientious, *then*, assuredly, any addition to the number of either must unavoidably lessen the total amount of income to be divided among them all; and consequently ought to prevent any considerate parent from devoting his son to the study of either law or medicine, at least so long as both professions continue to be so overstocked as they *are and have been* for many years past.

The following brief illustration of the difference between the sources of income, upon which lawyers, doctors and farmers necessarily depend, must place this matter in a point of view, the justness and truth of which no man in his senses can deny. For instance, the *farmer's thrift* depends upon the thrift and the health of all other trades, professions, and callings, for *all* are *his* customers, inasmuch as *he* produces the necessaries of life which all want, and must have, in proportion to their appetites and means of buying. On the other hand, the *lawyer's thrift* depends upon the number of disputes and quarrels in regard to property, of injuries to persons or character, and of frauds and crimes which *may* be committed within the limits of his practice; for, be it remembered, that none of these things are necessary incidents to society, although of too frequent occurrence. And the *doctor's thrift* depends on either the real or supposed unhealthiness of the persons among whom he lives. If few or none are litigious, few or none slanderous, few or none perpetrators of fraud or crime, the lawyer is in some danger of starving, instead of growing rich; whilst the physician is in quite as bad a predicament, should there be little or no sickness, few or no diseases. True it is, and most lamentably true, that such a condition of society cannot reasonably be anticipated; but we may confidently cherish the hope of a nearer and nearer approximation to it, if the great, the vital causes of *temperance* and *popular education* continue to advance, and to gladden the hearts of all true lovers of their country, as we now have every reason to believe they will. And so sure as they do, just so *sure* will fewer instead of more doctors and lawyers become necessary. But the well being of every community will always require some of each profession, and I am one of the last men who would maintain a contrary opinion. I have too great an esteem, too sincere a regard for the worthy men of both classes, to say any thing in disparagement of either good doctors or good lawyers, for I am happy to believe that many of them are among my best friends. All I wish is, to remind my brothers farmers of the old proverb, that we *may* have too much, even of a good thing; and to beseech them to recollect, that in our own profession there is still more ample room for more, many more recruits.

In making this assertion, I am fully sustained by the facts which our late census has disclosed in regard to our own state. But at present, I will refer only to those which more immediately concern our own comparatively small county. According to the authority which I have consulted, Essex contains only 280 square miles, or 168,000 acres. By the last census, our whole population in this county amounts to no more than 11,309 persons. Now supposing that three-fourths of this number are engaged in agriculture, and that only two-thirds of them are capable of labor, which seems to me a fair estimate, as none under ten and over seventy years of age ought to be counted, we shall have no more than 20 and a small fraction, who can properly be called agriculturists, to every square mile, which is a little over three to every hundred acres! This, I think, amounts to a demonstration, that we shall be in no danger whatever, for many, many years to come, of being overstocked with farmers and cultivators of the soil. Nay more, it proves most clearly, that if we consult the interest of Virginia husbandry, and the great national interests partly dependent thereon, we shall use all the fair means in our power, to induce our sons

to devote themselves to agriculture, in preference to any other profession. One of the most obvious of these means is, to improve our own knowledge of it, both by study and practice; for then we shall have the great advantage of addressing their understandings, by the all powerful agency of example, as well as by that of precept. When a parent heartily works by both, seldom indeed will he fail to succeed with his child in any thing; for among all the admirable lessons of wisdom, which we derive from that great store-house of soul-saving knowledge, the Holy Scriptures, there is not one of more practical utility, not one of more vital importance, than *that* which inculcates upon parents the absolute necessity of first doing as they would wish their children to do, before they have any right to expect good conduct from them. By the same divine authority, we are assured, that if we will bring up our children in the way in which they should go, they will not depart from it. If, therefore, any of my brother farmers who now hear me, desire that their sons should follow their own profession, as I certainly think they ought, these sons should be brought up to it, educated for it, and taught to love it. The very effort to do this, will benefit yourselves full as much as it will benefit them; for there is nothing which will operate so effectually, to make us sensible of our own want of instruction in any particular branch of knowledge, as the attempt to instruct others therein. This will soon expose to us our own self-conceit, without a consciousness of which, nothing can ever inspire us with an efficient desire to seek more information in regard to our profession, inasmuch as we foolishly imagine ourselves already possessed of all that we need have.

Should any of my hearers be in this self-complacent, opinionative condition, a condition so delectable to the individual himself, but so truly ridiculous to all others who behold it, I beseech him to try earnestly, if it be but for a single day, the experiment of teaching one of his sons the principles and practice of agriculture. And if this one effort did not so far open his eyes to his own ignorance, as to cure him effectually of all overweening confidence in his own knowledge of his profession, I should not hesitate to affirm of that man, that he was doomed to live and die, without any farther acquaintance with husbandry than he then possessed. To expect *him* to improve would be quite as hopeless a thing, as to look for it in one who was entirely destitute of all the faculties which render man an improveable creature.

Before I conclude, permit me to make one or two other suggestions which I deem very important to the successful operation of an agricultural society. The first is to make every member, as far as practicable, a *working member*, instead of what is generally called "a sleeping partner." To do this, the best method, I think, is one lately suggested by Mr. Ruffin, editor of that excellent paper, "The Farmers' Register." He recommends that the constitution of every agricultural society should require each member, who is a farmer, to make annually and report the results of at least three experiments, on a scale suited to his means, in regard to some disputed questions in agriculture; that at least half the funds of the society be offered in premiums for the best of these experiments; and that a fine of one dollar be imposed for every one that each farmer fails to make. This would keep all the members on the alert; and would certainly elicit, every years, some useful information which might be beneficial to all.

My next suggestion is, that in every case where premiums are offered, it should never be forgotten, that the sole purpose which they ought to aim at accomplishing is, to obtain the greatest results at the least expense of labor and materials. For instance, if the premium be offered for the greatest produce per acre, of any crop, let it always be made an indispensable condition that authenticated statements should be produced, not only of the quantity, but of the quantum and kind of manure, and labor expended in making it. Again, if the premium be offered for stock, let it be required that the whole process of rearing and fattening be stated in a manner equally well authenticated and particular. The same regard to economy should regulate all other premiums, not only to enable poor farmers to compete for them with a fair prospect of success; but because every agricultural society should make it one of the chief objects of its efforts to promote and encourage economy in all farming operations whatever. Without a due regard to *this*, no farm can properly be said to be well managed, since the net profit may be reduced to nothing, however large the crops, unless the various expenses in making them be constantly kept within the narrowest limits compatible with the progressive improvement of the farm, and the regular increase of the owner's clear income.

And now, my friends, I will no longer detain you from organizing your society, but conclude with the full assurance, that if properly sustained, it will rapidly improve you, both in the knowledge and practice of your profession; it will strengthen your conviction, that no other vocation contributes so much to independence, so much to health, plenty, and competence, if not to great riches; that it will enable all industrious, frugal owners and cultivators of the soil to provide well for themselves and families, to give much to them that need; but above all, to impart to their children that sound moral and religious education, which is the best, *incomparably the best legacy* a parent can leave to his child; for it ensures to him, so far as human means *can* do it, happiness both in this world and the world to come.

TO GUARD SHEEP FROM BEING KILLED BY DOGS.

From the American Agriculturist.

Perhaps one of the greatest obstacles to the keeping of sheep has been the savage destruction made among them by worthless curs kept throughout our country, for no other reason, that we could ever imagine, than to gratify the fancy of their owners. If these animals were kept constantly chained up where they could do no harm, no fault would be found; but when suffered to run at large and become public destroyers, it is quite another affair, and we hold every one justifiable, nay, a positive duty on their parts, to shoot all dog prowlers, without any more hesitation than they would a mad wolf.

The importation of the large Spanish shepherd dog has been recommended, as he will invariably attack and kill any dog that approaches his flock, but this would be an expensive and troublesome measure, and it would take a long while to breed a sufficient number of them here, before they could become generally effectual. During our recent visit to Kentucky, we learned a very simple, and at the same time profitable way of guarding sheep, which is this:—

Put a few active cows, with their sucking calves, in the same pasture with the flock—five would probably be enough for several hundred sheep, to which add five active three year old steers, and as many more two year olds. Take a gentle dog into the field, with a long light cord about his neck, the end held in the person's hand accompanying, to keep him in check, and then set him on to the sheep. The cows, thinking of their offspring, will immediately advance to head the dog and guard the calves, the steers will follow their example, and the sheep retreat behind them. Thus continue a few times, till the steers are well broke in, when the cows can be taken away and they will inevitably gore any dog to death that dare persist in attacking the flock. However brave a dog may be in other matters, the moment he attacks the sheep, he seems to be conscious of the ignominy of it, and as if conscience stricken, becomes a coward, and will run at the slightest approach from other animals.

When steers arrive at the age of four years, it is generally requisite to remove them to better pasture than is required for sheep, for the purpose of fatting, or they are wanted for the yoke. But just before this is done, add as many two year olds as you wish to remove of the older ones, and the three year olds left will soon break in the young ones, and so the system can be annually kept up as long as requisite.

For these guards, we would recommend a small active race of animals, with sharp horns, as they would more effectually gore and toss a dog, and it will require a small active animal to support itself on feed, that is generally as short as sheep pastures usually are. The hardy red cattle of New England would be admirable for this purpose, or indeed any active native animals, those chosen from the hill or mountainous districts would be best, as more fleet and pugnacious when required. We are told by hunters, that it is thus the wild buffalo protects himself, on the vast plains of the west, from the attacks of savage bands of wolves, and they not unfrequently afford protection to whole herds of deer. Mr. Hart, of Kentucky, defended the deer in his park by the elk, a single pair of which, would be sufficient to guard hundreds of them, as they would run down the fiercest dog in a few minutes, and cut him in two by perhaps a single stroke of the sharp hoofs of their fore feet.

IRISH POTATOES AND OATS IN NEW LAND.

From the N. H. Monthly Visitor.

We have heretofore endeavored to impress upon our readers the value of our rough mountain lands. There yet remains much land in the upper counties of this state considered of little value that may be made valuable. In conversation with Winthrop Folsom, Esq., of Dorchester, a few days ago, we gathered the following facts:

Four or five years ago he purchased a lot of eight acres of uncleared rocky land, for which he gave three dollars per acre: this land, covered with a growth of wood, he cut down, cleared, burnt and fenced at an expense of eight dollars per acre—making the cost of land eleven dollars per acre. It was planted with potatoes: he charged himself one dollar for every day's work done, and twenty-five cents per bushel for the seed potatoes. He called the potatoes raised that year on the ground worth sixteen cents the bushel; and he found the gain of this year's operations, above the cost of land and clearing and the expense of seed and labor, to be ninety dollars, or nine dollars per acre. The next succeeding year he raised on the same ground four hundred bushels of oats: since that time the same land has produced a decent crop of hay, and is now good pasture land.

Mr. Folsom has more recently purchased a lot of three hundred acres of these wild lands at the price of one dollar an acre. On this land he has commenced clearing. His first clearing was fifteen acres at the cost of eight dollars an acre. His first crop of potatoes on this ground was 3,100 bushels. Three thousand bushels sold to the starch manufacturers at one shilling the bushel, brought $500—one hundred bushels drawn home worth $17—making the year's product $517. The cost of land, fencing and clearing, $160, would leave the clear gain of this year's operations on these fifteen acres, three hundred and fifty-six dollars. The second year, (which was the last year, when the crop suffered much from drought) the same land produced 475 bushels oats, worth at 50 cents, 237.50, and 14 bushels of rye worth $1.00, making $251. After the two crops were taken off, it would not be high to value this land at five dollars the acre.

The method of planting the potatoes is extremely simple. After the ground has obtained a good burn, the planter proceeds with a bag of cut potatoes swung over his shoulder—strikes a sharp hoe into the ground through the outside root turf—covers with the foot, making each hole at the distance of about eighteen inches in the row, and the rows three feet apart. Planting in this way makes three fair days' work to the acre, worth $2.25. The digging of an acre of potatoes at four shillings per day, six days' work, is worth $4. No hoeing during the season is necessary; and so well does the seed operate in the ground, that the vines often grow to a sufficient size to cover the land. The whole expense of raising potatoes on burnt ground, after the ground is cleared, Mr. Folsom informs us, will not much exceed six cents a bushel.

SOWING CORN BROADCAST.

From the American Farmer.

In the Farmer of April 20th, I observe over the signature of "Ledyard" some inquiries in relation to sowing corn broadcast, and the best method of securing the crop.

Having tried the experiment last year I offer a

few suggestions as the result of my experience. I sowed a few acres with a view of ploughing it in as a green crop for the benefit of the soil, but was tempted, by its luxuriant appearance and a scarcity of other provender, to make use of it for that purpose. The quantity of seed sown was about 2 bushels per acre. Perhaps in a very rich soil, the use of a smaller quantity of seed might be attended with the objections named in the remarks which follow the inquiries of your correspondent, viz.—"the tendency of weeds to check its growth."

After the ground is well harrowed and sown, I would recommend your correspondent to make use of the cultivator to cover the seed—which by the way I have found an excellent improvement for covering seed wheat. The ground should then be rolled smooth, which is all that is necessary to be done until the time of harvesting arrives. My crop was cut just at the time the grain began to harden—and the lower leaves of the stalk were becoming shrivelled. The fodder was suffered to lay on the ground for a day or two until the stalks had become sufficiently wilted, to be made use of as *bands* for tying the fodder in *small* sheaves; after being bound the sheaves are set up in small shocks of about one dozen sheaves each, and *capped* by placing one sheaf on the top as a crown to shelter the shock from rain. In this state it remained until perfectly *cured*, when it was carted off and stacked up in a convenient place for feeding. I find this far superior to the "whate straw" of our friend Paddy, for it don't require *any thing at all*. E. P.

P. S. With respect to the proper time of sowing, I would suggest that the usual time of planting corn is the most fit season where the crop is to be used as dry fodder.

Balt. Co., April 21*st*, 1842.

THE FRUIT CURCULIO. FRENCH RECEIPTS TO GUARD AGAINST THE BLACK WEEVIL.

To the Editor of the Farmers' Register.

Hillsborough, N. C., April 8*th*, 1842.

I send you the following fact, in confirmation of the view you have taken of the application of marl or shells to the soil around fruit trees. I see that Mr. Downing, of Newburg, takes a similar view of the matter, and recommends clay.

The fact to which I allude is this. A few years since, while at the house of a very intelligent farmer, of Lincoln county in this state, I was forcibly struck with the lively and *clean* appearance of his plum trees, which were then loaded with fruit. On inquiring of his mode of treatment, he remarked that the only secret in the case was, to set them out by the *road side*, (as his were) or along some path, where the ground would be trodden down as hard as possible.

It would appear therefore, that the rationale of the thing is not to be sought in the shell marl or in the clay, but in having such a hard pan of earth around and under the trees, that the insects which infest them cannot get a lodging place in the soil.

This subject reminds me of numerous receipts, against various insects which are so troublesome to agricultural and domestic economy, that are found in a French work, entitled "Secrets concernant les Arts et Métiers," published in 1790, in four volumes. In reading it over lately, it occurred to me, that possibly some of the secrets for destroying insects might be valuable; and if so, that I would be doing good service to furnish them for your paper. I have no means of knowing whether they are useful, and will therefore send you a specimen, and let you judge for yourself. If you think them worth publishing, let me know, and plenty more of the secrets shall be forthcoming.

—

Mode of protecting grain from the weevil and other insects.

Soak a woollen or linen cloth in water, and after wringing it out, spread it over your grain. In two hours the weevils will be found attached to it.

Against weevils.

Take as much lie as is necessary for washing over your granary, in which boil a quantity of ox-gall, (an excess need not be feared,) and wash your granary with the mixture.

Another mode.

Spread branches of the elder over your grain heap, and the insect will retire to the walls, from whence it will be easy to sweep them up and burn them. To make the odor more effective, the leaves and branches may be bruised.

Another.

After the grain has been removed from the granary, spread a large quantity of the branches of the box over the floor, and let them remain till the grain is put in; when they should be put along the walls, partitions, joists, &c., as well as on and around the grain.

Another.

Let your barn be emptied and swept, after which let a flock of sheep lie in it for six weeks. The odor of these animals will kill the weevils. Should they make their appearance again, the following method should be adopted:

Another.

Place in the middle of your barn, or granary, a large iron pan of burning charcoal, closing the doors and windows tightly. Cut three or four old shoes into small bits and throw them upon the fire, to which may be added the hoofs of horses, &c. The fire should be kept up for three or four hours. The strong odor of this smoke will infallibly kill the weevil, &c. This process should be repeated every year before housing your grain. It also drives away rats and mice.

[I think this process would be pretty sure to kill men!]

Another.

Sprinkle the floors and walls of your granary with a decoction of garlic, well steeped in a sufficient quantity of salt water. The odor of this is no sooner diffused than the weevil dies or goes away.

Wormwood, rue, savory, lavender, green coriander, and all plants of a strong odor have the same effect.

Another.

Melt Burgundy pitch, and by means of a bit of tow make a slight coating of it upon the shovels used for stirring the grain heaps, and then rub them over with the oil of petroleum. After turning the grain with them two or three times, the weevils will disappear. It will be necessary to renew the oil and pitch whenever they become detached from the shovels.

The above are some of the first "secrets contre les insects and les animaux nuisibles," and are a fair specimen of the whole. Some of the processes I should judge to be inert. You can perhaps determine whether *any* of them are valuable. Very respectfully and truly yours,

M. A. Curtis.

[The foregoing recipes all apply, it is presumed, to the *black weevil*, a small insect of the beetle tribe, which has wings, but is not known to fly, which lives through the winter, and infests mills and granaries which have grain always in them, so as to furnish a regular supply of food to the insects. The moth or flying weevil, which is so much a greater depredator on the crops of negligent farmers in lower Virginia, is not common in France, even if certainly existing there. Cleanliness in barns and granaries—cleaning out all the old grain, and all the grain some part of every year, is the best preventive against the black weevil. And the flying weevil, though even a more formidable foe, usually may be perfectly guarded against by care and attention, with a proper knowledge of the habits and especially the mode of propagation of the insect. See a long article on this subject at page 325, vol. i. Farmers' Register.—Ed. F. R.

GRASSES AND GRASS CULTURE OF FRANCE.—CONTINUED.

Translated from "Le Bon Jardinier," for the Farmers' Register.

Luzerne, Medicago sativa.—The great advantages of this plant, the most productive of all of those employed in artificial meadows, are well known. It prefers good land, deep, sound, well cleansed, and manured the year before it is sown; but it succeeds in many soils of different natures, but not on those which are grassy or have clay on the surface, or are very poor. If it is manured at the time of sowing it is necessary to do it with compost well pulverized. The considerable product and the great durability of lucerne, owing very much to the facility with which the roots penetrate the earth to a great depth, should have the effect of bringing it into universal cultivation. In situations that are either low or near woods, or that are from some cause subject to late frosts, it is prudent not to sow it until May. In some cantons it is not uncommon to see it postponed until the summer. In dry and light lands it may be sown early in the autumn with barley or rye. The ground having been well prepared the seed should be sown with that care which their fineness renders necessary. To keep up the product of a lucerne field, and to prolong its durability, it is proper to top-dress it in the winter, or in the commencement of spring, with well decomposed manure or with the ashes of turf or coal, or what is still better, with ground plaster, a substance which produces on all plants of the leguminous family the most astonishing effects. Plaster should be sown in a spell of damp weather when there is a prospect for rain; it may be done not only in the latter part of winter, before vegetation has commenced, but also in the spring and summer when the first and second growths have begun to be developed. Few persons are ignorant of the frequent accidents that occur from grazing the aftermath of clover and lucerne; when cattle are permitted to go on it before the dew has been dissipated, or after a rain, they become inflated, and often perish. Farmers, therefore, cannot be too careful in this respect, as well as in employing it green in the stables; for if given there whilst wet, or in too great quantities, it will occasion similar accidents. They sow forty pounds of seed per hectare.

Luzerne rustique, Medicago media.—There grows naturally in France a lucerne similar to the cultivated species, but which differs from it in its disposition to elevate its stalks and to grow more erect, and in its being more tardy to put out in the spring. This is the variety which I here call the luzerne rustique. From many observations that have been communicated to me, and from those which I have made myself, I have reason to believe that it is more hardy and less difficult to suit with a proper soil than the *medicago sativa*. It is very vigorous, and often produces stalks more than four feet in length. Athough the experiments that I have made are not sufficiently advanced for me to form any certain opinion, yet this plant appears to me to possess sufficient interest, to render it my duty to point it out to farmers, and to call their attention to it. It is an intermediate between the common lucerne and the *Lucerne faucille*, (*Medicago falcata,*) and I think, without being certain, that it is the plant designated by Persoon, in the Synopsis Plantarum, as the *Medicago media*. The *Luzerne faucille*, the culture of which has been frequently recommended, has always, in the attempts that I have made, appeared very inferior to the variety of which I write; but as it grows naturally on the poorest lands, it deserves to be submitted to the proof of culture. After continued attempts for many years I have determined to give up entirely the luzerne faucille. Although it grows naturally on poor chalk lands, yet sown on these same lands, the plants near one another do not grow with any of that vigor that they possessed when growing isolated here and there. Another objection is, that the stalks have a decided tendency to lie upon the ground. Finally, to obtain any decided profit from it on poor land, it is necessary to ameliorate it very much; in which case the medicago sativa is far preferable. Although the *Luzerne rustique* succeeded with me, yet it did not

seem to possess the decided advantages of the ordinary variety. But Mons. Descolombiers, who has also brought it into cultivation, informs me that with him it "grows vigorously, dry, and not deep, and not watered, in the midst of a crop of *brome* and yarrow; and, in short, that it most justly deserves its name," (the hardy lucerne.)

Lotier Corniculé, Lotus corniculatus.—Little is as yet known of the culture of this lotus, but it certainly deserves to be studied. In meadows, where it is frequently found, it is valued; although, from the shortness of its stalks, hay cannot be made of it. It is good for pasturage, grows readily in dry lands, and maintains its vegetation during the summer. It is suitable for most purposes for which the white clover is employed, and is often preferable, particularly in adorning grass plats, where its yellow flowers have a very pleasing effect. Unfortunately there are so few seed, and they are so difficult to collect, that the culture can never be widely extended.

Lotier velu, Lotus villosus.—This species resembles the last so closely, that many botanists have looked upon it as only a variety, but it is a decidedly distinct species. It will grow on lands more moist, is more erect, and is better supplied with leaves. From its great longevity, which I have observed both in its wild state and in experiments that I have made, I have no doubt that the *Lotus villosus* would be a good plant to cultivate, alone perhaps, but at least in mixtures, to form natural meadows. The grain is much more abundant than in the other variety. It should be sown in March and April, about sixteen pounds to the hectare.

Lupin blanc, Lupinus alba. It is only in the south of France and in Italy that the excellence of the manure that this plant affords, when turned under whilst in flower, is known. The grain soaked in water is a good food for cattle, and it is used when green as pasture for sheep. One of the chief advantages of the lupin is that it prospers on very poor land, such as a coarse sand, a ferruginous soil, or a poor clay, and affords means by which to enrich them; it is rather sensible to cold, and should not be sown in the climate of Paris until towards the middle of April.

Lupuline, Medicago lupulina, has the leaves and appearance of a clover, and for that reason is called sometimes *yellow clover*, or *black clover*, which names are derived, the first from the color of the flower, the last from that of the husk of the seed vessels. Its culture has for a great while been confined to the neighborhood of Boulogne, but it has been lately spread considerably, into the interior of France. It is valuable because it will grow on inferior lands. It is biennial, and can occupy in the cultivation of rye lands the same place that clover does on wheat lands. The forage that it affords is not abundant, but is fine and of good quality, and very acceptable to cattle. But the lupuline may be more advantageously used as pasturage for sheep than by converting it into hay. It is generally sown in March, at the rate of thirty pounds of seed per hectare.

Pois gris, Pisum arvense, as forage, is very much esteemed, particularly for sheep. It is an annual, and is of very rapid growth. It is good to sow on fallow lands, and if cultivated properly, it will reduce them into excellent order for the ensuing grain crop. Moist wheat lands are best suited to the Pois gris, but it will also succeed on rye lands when they are in tolerably good heart. It is well to manure it, when it is to be followed by a crop of grain. They usually sow it broadcast, and cut it sometimes when it is in full flower, but more generally when the most of the pods are formed, and dry it for winter use. Two spring varieties are the most common. One is early, and is sown in March; the other is not so forward, and is not sown until May. A third variety, called the *Pois gris d'hiver*, which is sown in the autumn, has lately been brought into cultivation, and seems to be very desirable, particularly in arid soils. Pois gris is put generally in those foragenous mixtures called *dragées*, (meslin or mixed grass.)

Sainfoin, Hedysarum onobrychis. The good qualities of the sainfoin are too well known to render it necessary for me to point them out; but I may insist with much utility on the faculty that this plant possesses of succeeding on indifferent lands, whether sandy and gravelly, or very chalky, and on its merit in ameliorating them very much. Among the examples of its ameliorating effects, I will mention that furnished me by Mons. Yvart, as having taken place on his farm, *Maisons*, near *Charentou;* he has with sainfoin converted into wheat lands fields of gravelly sand, from which he could previously, in spite of all his efforts, only obtain rye. The demonstration of these effects has been so plain, and the example so influential, that by degrees a great part of the lands of the plain of Maisons has by the same means undergone a similar transformation. When one lays out a meadow of sainfoin for mowing, and wishes to preserve its durability for as long a time as possible, the grazing the aftermath should be sedulously avoided, particularly in the first years. There are cases, particularly in indifferent ground, where they sow it expressly as pasturage for sheep; it will then last but a short time, but is still a great resource for food. They sow it generally in the spring, but sometimes in the autumn, and almost always with a grain crop. The variety, *Sainfoin a deux coupes*, or *Sainfoin chaud*, first propagated in the environs of Peronne, by Mons. Pincepré de Buire, has been considerably extended into France in a few years. It is more vigorous, is stronger and more productive than the ordinary sainfoin, and it yields a second abundant mowing, whilst the other only produces an indifferent aftermath. Many farmers who have adopted it have informed me that it required better land than the ordinary variety. As it is to be presumed that this is only a variety in some manner artificial, obtained by being cultivated for a great while in good lands, persons who sow it in indifferent lands should from time to time change their seed, to obtain constantly produce decidedly superior to the ordinary sainfoin. Its leaves being much larger, and harder, and the seed much coarser, it is necessary to sow it thicker. Mons. Tirris, proprietor at Forcalquier in the department of Lower Alps, has brought about an agricultural revolution, not only on domain, but in all the adjacent country, by the introduction of a grass that he calls the Spanish sainfoin, and which he believes to be the veritable *sulla.** But this plant, of which he sent me a

* See the *Annales d'Agriculture*, July, 1828.

few seed, has proved to be the *Sainfoin à deux coupes*, of which I have been writing. The real *Sainfoin d'Espagne*, *Hedysarum coronarium*, has not yet, I think, taken a place among our forage-nous plants, although it would probably succeed in our southern department.

Grand trèfle Normand.—Mons. de Laquesnerie, a learned agriculturist, discovered this variety of clover, and had the kindness to send me some seed of it. The experiments that I have made with it, have shown me how accurately he described to me the details of this plant. The Norman clover is much taller than the common trefoil, and generally yields but one crop, which, however, is often equal to two mowings of the ordinary clover, its hay is coarser, and the plant appears to be more durable. Is this clover to be preferred to the ordinary variety? I will not undertake to resolve this question, which indeed may be susceptible of different solutions, in different soils and under different circumstances. It has been so recently introduced, that it is impossible for me to form a correct opinion as to its value, but I have thought proper to point it out to farmers as an interesting subject for experiments and observations.

Trèfle d'Argorie, is another variety of red clover, which has been for some years cultivated in Switzerland, and which appears to possess some important qualities. I have been assured that it will last for four or five years, from which character it has been called the perpetual clover. I have not myself been yet able to verify this fact, but what I have observed in it, and what appears to me still more interesting, is the very decided disposition that it has to increase its stalks, and that it is at least fifteen days more forward than the common variety of clover. It is also very vigorous, and has long leaves. If the qualities which have shown themselves in this instance, in this variety, are confirmed by numerous proofs, and if it preserves them without any apparent depreciation, for many successive generations, it will be certainly a desirable acquisition to agriculture.

Trèfle incarnat, *Trifolium incarnatum*, affords only a single mowing, and its hay is inferior to that of the common clover; yet there are few varieties of the trefoil that can be rendered more serviceable in agriculture. Cultivated almost without expense, without care, and without deranging the order of the crops, it yields a most abundant crop of hay. It possesses, in a very eminent degree, the merit of being precocious; and, whether as pasturage or to be cut green, affords resources for feeding cattle before any other plant. They sow this clover in August, or early in September, generally on the stubble fields, after having turned them over by a light working with the plough or extirpator. This working, or rather moving the surface of the soil by repeated harrowings, is necessary for the clean seed, which it is necessary to cover with care. But when it is sown in the pug, it is sufficient to spread it on the stubble without any preparatory working, and to pass a roller over it. This is a very good plan, particularly when one wishes to sow it directly after harvest. One may perceive by this with what facility the agricultural condition of countries destitute of grass, particularly those where the triennial rotation is in use, could be ameliorated by the cultivation of this plant. Let a farmer for example sow a portion of his oat stubble, say a fourth part in it. About the first of May, if he wishes to cut it green, from the 15th to the 25th, if he wishes it for hay, all can be taken off, and he will then still have time to work it properly. Thus, without any derangement, he will have obtained from this part of his stubble field an abundant crop of hay between the harvest and the time for ploughing. The *Trifolium incarnatum* is very valuable to sow in places where the red clover is missing, which is done either by spreading on them the seed in the pug, or by raking in the clean seed. Almost all wheat and rye lands, provided they are sound, will produce this clover. I have sown much, and I have seen much sown on soils of very different natures, and with me it has only failed on lands that were excessively chalky, and that were very much spewed up by the frost. Sometimes our winters destroy this plant, but that accident is very rare, and although there is an instance of it in 1820, yet that should not prevent its culture from having a rapid progress. They sow thirty or forty pounds of the clear seed to the hectare, and when it is sown in the pug it requires from ninety to a hundred pounds.

Trèfle de molineri, *Trifolium molinerii.*—They designate by this name a wild trèfle incarnat, which grows commonly in the centre provinces, and in the north of France. It is chiefly distinguished from the cultivated variety, by the much paler color of its flowers, which are at first of a dingy white, and afterwards assume a pale red, or flesh-colored tint. But this difference, although general, is not constant, and although there are some other apparent differences, as the length of the heads of the flowers, &c., I do not know that they are sufficiently marked to permit these plants to be botanically separated. However, notwithstanding their close botanical conformity, there is a very decided difference in their dispositions, and in their mode of vegetating. First, the *Trifolium molinerii*, grows spontaneously in the north, where the other has only been introduced by culture; it is also slower in the germination of its seed and in its developement; it has less disposition to send forth stalks; and I have seen it last two years, whilst the *Trifolium incarnatum*, sown by the side of it on the same day, was entirely dead at the end of the first summer. That which first induced me to try the *molinerii*, and to compare the analogy of that and the *incarnatum*, was that, having often met with it about Paris, I thought that, accustomed for a long succession of generations to our climate, it would be more hardy, and resist more constantly the cold of our winters, than the southern race, and that the hay crop would thereby be rendered more certain. I have as yet obtained no decisive proof of this, and I should say, on the contrary, that it appears to me in many respects inferior to the cultivated variety. I have, however, thought it my duty to place before farmers this account of these experiments, because they have a really useful design. The *Trifolium incarnatum*, is a plant of so much value in agriculture, that it will be of great interest to our country to obtain a variety that will not suffer from cold. In a work recently published, the *Trifolium molinerii* and the *Trifolium incarnatum* are presented as being one

and the same. That may be true, botanically speaking, as I have said above, but in culture it is otherwise. I have cultivated the first for many years, and I have made comparative experiments with them both, of many acres at a time, and have always found decided differences between them. I am not singular in this opinion; many practical men, who have tried both of these plants, have come to the conclusion at which I had arrived. I will mention among them that distinguished agriculturist, Mons. Descolombiers, whose opinion on this subject coincides entirely with mine. A third variety has been announced and recommended, by Mons. Juery, of Toulouse, it is the *Tréfle incarnat tardif.* Its name indicates its quality; it is sown and cultivated like the common variety, and comes in later. According to accounts published at Toulouse, this clover does not commence to flower until the other variety is out of bloom. But in the experiments that I have made, both in the environs of Paris, and at Gatinais, I have found only the difference of five or six days in the blooming of the two varieties. Perhaps I may not have received the decided species, or this difference may be owing to the difference of the climate, which has more effect on the early than on the later variety. Be that as it may, the culture of it has made considerable progress in the south. Mons. Descolombiers, has informed me that in the department of Allier, he and his brother-in-law, Mons. the Marquis Saint George, have sown much of it, and have derived positive advantages from it. If one is obliged to resow, with the tréfle incarnat, a clover field that is too thin, this late variety should be very much preferred, as it accommodates itself better to the mowing of the red clover, than the ordinary variety.

Vesce commune, Vicia sativa, is an excellent annual forage, is suitable to render waste lands useful, and offers many other considerable advantages; the most important of which is that it may be seen as late as June on strong and moist land, and in that manner affords an opportunity of providing against a scarcity of hay, if the crop in the meadows should fail. There are two main varieties of tare, that of the spring, which is sown in March, April or May, and sometimes in June, and that of the winter, which is sown in the autumn. Both prefer good land, which is rather stiff than light. A considerable quantity of moisture in the winter will destroy the winter tare; it will grow more readily on dry and light soils than the spring tare, which, on the contrary, delights in moisture, particularly when sown late. It is necessary to cover the seed with care, to protect them from the pigeons, which are very fond of it. They cut the hay whilst the plant is in blossom, or when a part of the pods have commenced to die, or indeed after their entire maturity, if one desires the grain rather than the hay. The tare is a very good food to give green in the stable or to graze, but it should be used with the precautions that are necessary to be taken with all grasses that are very succulent and nutritious; for given too damp and too abundantly, it affects the cattle not less dangerously than clover that is too moist. The ordinary quantity of seed that is used is about 26 decalitres per hectare. It is well to sow a little oats or rye with the tares to support them.

La Vesce blanche, Vicia sativa alba, is less common than the two preceding varieties, but it is just as valuable as forage, and in addition, its white and larger grain affords a means of subsistence to man. In many cantons the inhabitants use it to make pea-soup, or use its flour in their bread, mixing it in small proportions with wheat flour. Many other varieties of tare might be usefully cultivated.

Ajonc, Ulex Europeus, Furze, is an extremely thorny shrub, a native of the uncultivated lands of Europe. The abundance and the durability of its yellow leguminous flowers would render it an appropriate ornament for pleasure grounds, did not the sharp and hard thorns at the ends of the branches and leaves render it objectionable. It is very good for making inclosures, which are almost impenetrable, for which purpose, after having sown it on the sides of ditches in March, they protect its young shoots from the attacks of cows and horses, which will eat it with great eagerness; which circumstance first led to the cultivation of the furze, in districts which were destitute of meadows and artificial pastures. They sow about 30 pounds of seed per hectare, on indifferent, but well worked land, the second year they begin to cut the young shoots before the blooming of the plant, which takes place from January to March, after that year they cut it in the winter as they require it. They give it to the cattle, after having crushed the thorns under a mallet or a stone. This plant has also the advantage of furnishing very good fuel, and they grow it expressly for that purpose in a part of Normandy. The furze is said to be a fertilizer. They get very good crops of wheat after it, which is owing without doubt to the custom of burning the stumps and roots, on the land when they extirpate it. The small variety of furze, *Ulex nanus*, common about the environs of Paris, serves whilst it is young to nourish the cattle of the poor, and in the autumn furnishes them with the means of heating their ovens.

Lenthille à une fleur, Ervum monanthos, is cultivated in some parts of France, for its forage and its farinaceous grain. Without being very productive, it possesses qualities which render it valuable in some cases; for example, it succeeds in indifferent lands, where one can neither raise the tare on the pois gris. Its small and climbing stalks require the support of oats or rye, which must be sown with it. Its grain is used as that of the *lathyrus sativa* in making pea-soup. They have made great use of it for many years about the environs of Orleans, where it is cultivated under the incorrect name of *lathyrus cicera.* It is generally sown in the autumn, and stands the winter very well. I have for many years been acquainted with the value of this plant, both from the experiments that I myself have made, and from those of my enterprising neighbor, Mons. Valentin de Culloin, which are on a very large scale. The masses of forage that he has obtained from the *Ervum monanthos* and the *Pois gris*, on land that until then was thought to be incapable of producing a single truss of hay, are such as have already resulted in the immense amelioration of his farm. I cannot too earnestly urge upon farmers, who possess gravelly lands, and who are stinted in their forage, to introduce amongst them the culture of this plant, as I am

confident that they will derive very great advantages from it. I say gravelly lands, because on those of an indifferent chalky nature, on which I have tried it, it succeeds but poorly.

Ers Ervillier, Ervum Ervillia, is an annual, and is common in some of our southern departments. The vetch, without being tall, affords very good hay, and also produces a large quantity of grain, which is given to pigeons, but with care, as it is very heating. The hay participates largely of this quality, and should be given in very small quantities to horses, and only when one wishes to give them ardor, or to prepare them to undergo very severe work. I have been assured that this plant eaten green by hogs was certain death to them. The grain as food for man is also suspected, and persons should guard against the mixing it in meal for bread. One may see that I wish less to recommend this plant, than to warn persons against the danger of it, of which they may be ignorant. The vetch can be sown in the autumn but it will succeed better when sown in the spring. Turned under in flower, it is thought in some cantons to be the most efficacious of all vegetable manures.

Féverolle, Faba vulgaris equina.—The great utility of this bean is generally known. Its culture may be very much ameliorated in stiff and clay soils, where indeed it is but little known. It affords a good forage, whether cut when in flower or when the pods have been formed. They often use it in the composition of *dragées* and of *hivernages* (mixtures of leguminous grasses, and oats or rye, intended for green food,) but it is the grain which renders it most valuable. They sow the féverolle from the first of March to the middle of April, either broadcast or in rows; the last method is generally preferable, but especially when the soil is compact, when working is almost unnecessary for the plants. The cultivation of the bean crop is desirable, not only because it is one of the least exacting crops, but because it is the best of all preparations for wheat on clayey soils. Turned under whilst green, the bean is one of the very best of vegetable manures.* All of the varieties, of which there are many, can be useful in farming; but this particular variety is the best for turning in. The *highland bean*, which I obtained from England, where it is much esteemed, is very valuable on account of its productiveness. In the south of France, the bean stands the winter very well, and is very often sown in the autumn, but in the north, where the ordinary variety is destroyed by the cold, or at the least very much injured, they sow a variety which is more hardy, and which they call the *Féverolle d'hiver.*

Rue de chevre, Galega officinalis. Those who see the rue in gardens, where its bunches are so vigorous and thrifty would conceive a favorable idea of it and desire to try it on an artificial meadow. But although recommended in many works, it unfortunately appears from different experiments that this grass does not suit cattle, because they refuse to take it as hay, and will not eat it in the pastures. If no positive experiments have been made on this subject, (and I know of none that have been made,) it is desirable that they should be made, as it is known that cattle often at first will refuse food that is excellent for them, and will become very fond of it after many trials. If such should be the case with the rue, it would be valuable on account of its great vigor its considerable product and its remarkable durability. They sow about 40 pounds of seed per hectare.

Gesse cultivée, Lathyrus sativus, is an excellent animal forage. It is particularly fine for sheep, and is less heating than the vetch. It succeeds readily on lands either stiff or light, if they are quite moist. They sow it in March and April, and sometimes, in the south of France, in the autumn. They cut it either when it is in bloom, and feed it green, or after the first pods have commenced to die, and make hay of it, or they permit it to mature entirely, that they may obtain the grain. In many parts of France the inhabitants make very good pea-soup of it.

Gesse velue, Lathyrus hirsutus. Mons. the Baron de Wal, of Baronville near Givet, informed me of the success which he had with this plant as forage. Sown in the autumn it appeared to him to rank in utility with the winter vetch. I tried it, at his request, and find it very hardy and foragenous, but more backward than the vetch. It produces a considerable quantity of seed, smaller than those of the vetch, but which appear to be good food for pigeons, but when the forage is cut green, as it ought to be, the most of the seed remain in the pods. If this plant could be brought into the list of those that are to be cultivated usefully for cattle, it would be a great conquest over the useless weeds of our fields, for the *Lathyrus hirsutus* is nothing else at present.

Petite gesse, Lathyrus cicera, is a winter variety, and is as hardy and perhaps more hardy than the winter tare. It furnishes an excellent food for sheep, but is too heating for horses, and should be given to them only with great care. I should also say that its grain is an extremely dangerous food for human beings. In some cantons the people make meal of it to mix with other flour, in very small portions, for bread. It does not appear to produce any bad effect, if the proportion is very small; but in years of scarcity some persons having increased the proportion, some have died and others have been stricken by an incurable paralysis. I have been assured of this by the excellent and indisputable evidence of the late Mons. de la None, surgeon at Bourqueil, and it has been confirmed by Mons. Deslandes in an article published in the Journal des Maires. It is particularly necessary to give this fact publicity, as the culture of the *Lathyrus cicera* has extended very much in France within a few years, and this danger has consequently increased.

(I have extended this translation beyond my usual length, that I might send you all of the article on "Fourrages légumineux," at once. Red and white clover, and melilot, which came under the same head, I sent you in my first selection.)

---

* This fact, which is equally applicable to the various peas of this country, is, I think, well worthy of the consideration of Virginia farmers, who would, I feel confident, find it very much to their advantage to adopt this mode of using the pea, particularly as it grows with so much certainty and vigor, even on inferior land.

CORN CULTURE. BOOK FARMING. ORCHARD GRASS.

For the Farmers' Register.

I have derived much benefit, in the cultivation of my corn crop, by the use of the coulter plough recommended by Mr. J. M. Garnett, in one of the volumes of the Farmers' Register.

After the ground is flushed, and reduced by the drag log, I chequer it with the coulter plough, running as deep as I can with two strong horses. To mark the spot for the corn to be dropped, I have attached to the beam behind the coulter a small ploughshare. When the corn rises, I run the coulter plough deep on each side; and after thinning, I run the coulter plough through it one way, and cross with rank cultivators. This I repeat, alternating the ploughs and the cultivators, till I complete the cultivation. If the season be very moist and the grass becomes strong, I make the last ploughing with mould-board ploughs. This I do with some reluctance, as I am unwilling to turn the ground after flushing. I do but little with the hoe, and think but little is necessary. I am sometimes obliged to chop a rough bottom. In my neighborhood we had a continuing drought, from the middle of June to the first of August last year. The fostering rains which then fell restored verdure to the stalk of the corn, though many of the blades were entirely destroyed, and I made a good crop. The main cause, I think, was the deep shooting of the roots, by which they escaped the burning influence of the sun, during the continued drought.

I am a friend to book farming, founded on fact and experience: in proof I offer my steady adherence to the Farmers' Register. The philosophers are now pushing their theories to a great extent, and I think are disposed to mix too much chemistry with agriculture. I am by no means satisfied that the fertility of the glades, in the Alleghany mountains, is occasioned, even in part, from the evaporations of the Atlantic and Pacific oceans. I particularly distrust the philosophy of the German school, both moral and natural.

To those who are disposed to grow orchard grass, I would observe, that the crop often fails from defective seed. Those who supply the seed stores often desire to have the benefit of the hay and the seed, and gather it in its immature state. To get good seed the plant ought to be perfectly ripe, so as to serve for nothing but litter. A small piece of ground will produce much seed; from less than an acre and a half I last year gathered near forty bushels. If good seed be sown, either in March or September, it rarely fails.

I commenced my grass culture with eight acres, which I have extended to forty. The profit I think greater than I could derive from grain crops, on the same lands. I have an annual crop, and the only expense, cutting and saving the hay. The orchard grass which I sowed ten years ago is now running out, and has been followed by green grass, (Poa pratensis.) I cut a good crop of hay from it last year, and the aftermath resists the frost as well as orchard grass. My milch cows, with no other food, except when snow was on the ground, grazed on it till the 10th of December, without failing in their milk.

RUSTICUS.

Eastern Shore, Md., March 13, 1842.

DEBATE IN THE HOUSE OF DELEGATES ON THE BOARD OF AGRICULTURE.

From the Richmond Enquirer.

When the bill to provide for paying the expenses of the members of the Board of Agriculture came up on its third reading—

Mr. Strother offered a ryder providing that they should be paid for their past services, but that hereafter the Board should be abolished. He addressed the House at some length in opposition to the Board, and denied that any great focus of light would result from its labors. Who, he asked, were to constitute the Board? gentlemen, politicians, or farmers? If politicians were to form it, surely no value would result; and if farmers, what information would they convey which could not be obtained in another way? The Board met a short time since in this city, and informed us that they had turned their attention to the geology of the state and several other matters connected with its agriculture. Their first demonstration, however, was that they wanted their pay. Now, he took the position, that the information which the Board of Agriculture was designed to collect, could be obtained in a more tangible form from other sources. It was true, that the people were anxious on the subject of agriculture; yet they could gather from the papers all they desired to know, all that was useful, and all that the Board would be able to furnish. If the members of the Board would hide their light under a bushel unless appointed, if their wisdom would depart from earth with them, there would be some reason for putting them on this Board and paying them for giving it to the world. But not so, the agricultural papers were in the habit of receiving all the benefits of the information possessed by these gentlemen.

Mr. Kennedy was sorry to witness so much opposition to the measure now before the House. Especially did he regret the source whence it came. From his knowledge of the gentleman from Rappahannock, (Mr. Strother,) and that gentleman's known exemption from all that was illiberal or contracted, he had relied on him to sustain the measure. The objection urged against the measure was that it would do no good. Now, Mr. K. thought that it must be manifest to all who would take the trouble to examine into the matter. The operation of the Board was plain. It gave a stimulus and encouragement to county societies, and they afforded the means of obtaining information for the press, which re-acted on the people at large. The press, Mr. K. said, had done much, and had manifested a lively zeal in the cause of agriculture. Still, it had over and over again declared that knowledge was not to be acquired in so effectual a manner as through a report from a Board of Agriculture.

Last year a State Board was appointed. Recently it met here, not so much to give to the world the facts it had collected, as to organize a plan of future operations. They propose to establish a correspondence with every section of the state, with gentlemen of information and experience—each man giving the experience of himself and neighbors. By reference to similar boards in other states, some idea might be formed of the utility of which this one of ours would be productive. The books they had published contained

much valuable information. For the purpose of showing the benefit derived by a neighboring state, Mr. K. instanced the county of Washington, in Maryland—separated from his own county (Jefferson) only by the Potomac—a county possessing the same soil and advantages as Jefferson—exactly the same distance from market—and in fact no difference existing between the two, except that the taxes in Maryland are four times as high as in Virginia,—where land brought nearly $10 more per acre than it did in Jefferson. Nothing caused this but the system of cultivation, which resulted from the establishment of the Central Board of Agriculture.

Mr. K. said he could not let the occasion pass without expressing his deep regret, that Virginia should present such a spectacle, as she now did, of barren fields and deserted firesides. She had not improved with the time. She had not kept pace with her neighbors. She did not maintain her stand among the other members of the confederacy, and he greatly feared that she was losing the dignity of her position. It was only necessary to refer to her census and to her advertising journals, to perceive that her character, her talent and her wealth were fast leaving her and going to the prairies of the west. He appealed to gentlemen to do something to resuscitate the glory of the Old Dominion, and asked them if they were willing to stand by and see such a measure as this fall to the ground for the paltry consideration of two or three hundred dollars. On such a subject as this, he would not make an appeal to their sympathies, but to their liberality, to their sense of justice and to their intelligence.

Mr. Bayly regarded the ryder as incongruous. The bill provided for the future pay of the members of the Board, whilst the ryder repealed the bill itself. He should not vote for the ryder, though he might at a proper time be disposed to vote for abolishing the Board. After some remarks from Messrs. Strother and Bayly,

Mr. Leyburn addressed the House in support of the bill, and particularly in reply to the gentleman from Rappahannock, who, he said, seemed determined to kill the bill with hard riding —"head it or die." When he heard that gentleman denouncing this movement as a humbug, morus multicaulis as a humbug, all kinds of conventions, even the *Education* Convention as humbugs, he could not help coming to the conclusion that the gentleman himself had been a sufferer from the morus multicaulis mania. Gentlemen had said, that the papers would render sufficient aid to the cause of agriculture. Whilst Mr. Leyburn admitted their utility, he still contended that superior benefits would result from a Board of Agriculture, collecting information from every where, and affording that information to the press, to be condensed and placed in an attractive form before the people. All had heard of the American Almanac—a publication containing a vast number of important facts, and bought by multitudes of the people of the United States. Now, he thought that a Farmer's Almanac, such as they have in some of the states, gotten up by an enterprising man, and embodying the information derived from the labors of the Board of Agriculture, might succeed very well, and be of eminent service to the people.

Mr. Holladay said the question was now pending on the ryder, by which it was proposed to abolish the board. Last year, the board was established without pay—now, it was proposed to abolish it and pay its members for past services. This he considered singular. If the board ought to have been established, it should have been continued, and if so, it should be paid. He hoped gentlemen were not prepared to declare by their votes, that we were unwilling to do any thing for the cause of agriculture. Virginia was essentially an agricultural state. That was the main interest and occupation of her people. Was it not therefore our duty to do something for it? Were gentleman willing to say to the first, great, foremost interest, "we fold our arms and deny that we can aid you?" How, he asked, did the gentleman from Rappahannock (Mr. Strother) come to the conclusion, that no good would result from the establishment of this board? Did he go according to experience in his deductions? If so, where did he find proof of the inutility and inefficiency of such a board? Where was there a community, in which there was a board of agriculture, that had not improved in its soil and its agricultural productions? It was, he thought, vain to say that the propriety of the board was not demonstrated by experience. On the contrary, if we were guided by experience, why could not the same results be achieved here in our own state as elsewhere? Did our own experience show that no good had resulted?

Gentlemen had laid great stress upon the advantages to be derived from the agricultural papers. These journals were established by men who had given their attention to the subject, in its principles and details. They all coincided in declaring, that a board of agriculture should be established. As we had their advice to this effect, why not take it? The present board of agriculture was composed of men of high reputation and experience. They had testified strongly in favor of the advantages which would be derived from it. Did gentlemen here know better than they? Could they reasonably gainsay the opinion of these gentlemen, fortified as it was by facts and experience? They had no interest in the matter, but the high and holy motive of patriotism. They could derive no advantage from it whatever. They could gain nothing for their reputations, unless they did something for the state, by reforming her condition, and enhancing her agricultural interests.

The house had been told that they should be economical in expenditure. This board would cost $500 a year, but what was that compared with the benefit it was likely to confer upon the state at large? He (Mr. H.) was as much in favor of economy as any one here; still, he denounced as niggardly, the economy that would defeat a useful measure like this, for the sum of $500. He thought something should be done for an interest which paid so large a share of the taxes of the state. Let it not be said that nothing could be done for such an interest. Let an effort be made, and even if no good should result, we should have the consolation of knowing that we had made an effort for the cause.

Mr. H. again referred to the argument of the gentleman from Rappahannock, concerning the

agricultural papers, and contended that they, as had often been declared by their editors, were unable to collect the facts from the various sections of the commonwealth. To elicit the desired information from every neighborhood, the system of farming prevalent in each division of the state, to get at facts which the practical farmer will not come forward to give to the community himself, is essentially the design of a board of agriculture. The Legislature was in the habit of legislating for every interest and on all subjects. Yearly laws were enacted to take care of the terrapins, oysters, fish and wild-fowl of Virginia; *should it be said that we could and would do nothing for the great cause of agriculture?*

Mr. Crutchfield admitted the subject before the House was important, and a consumption of some little time in its discussion was excusable. He would, therefore, say a few words, though he despaired of carrying a majority with him in opposition to the measure. Agriculture, he admitted, was an important interest—the most important in the state—and if he could be convinced that it could be benefited by this measure, he should cheerfully go for it. As it was, he must call on his common sense to guide him in his conduct towards the propriety of it. He did not see why gentlemen should object to the ryder, by which the future operations of the board were to be discontinued. If so much benefit was to result from the board, why was it so slow to be perceived! Had not an effort to establish it been made year after year, and without success, until last winter, when it never could have passed, had provision been then made to pay its members? In former times, when there was a surplus in the treasury and when a majority of the legislators were farmers, all efforts to establish a board were useless. Last winter it passed without provision being made for pay, and without calling the ayes and noes. Years ago, the ayes and noes were always called successfully against it.

Mr. C. reminded gentlemen of the voluntary boards and societies which had been formed for agricultural purposes in different parts of the state. They had all flourished for a few years. There was one in Albemarle—where was it now? There was one in Spottsylvania, but it was waning away. These societies had given many speculative reports; yet Mr. C. said, that after a while they degenerated, and became like the reports of many of the school commissioners—a column appropriated for "remarks," and the whole of it blank, except the words, "nothing further since our last report." Mr. C. said he opposed the further continuance of the board, because he was convinced it would render no service to the state. Could he bring his mind to a different conclusion, poor as the treasury was, he would vote $500,000 to aid the cause. The proposition to pay the board for past services was a draft on the honor of the Legislature, which he could not consent to protest. He was willing to pay the board, and let it cease for the future.

Mr. Kinney said he was opposed to the ryder. The Legislature had done much for every other branch of knowledge but agriculture. It had established professorships of law, of medicine, and a military institute. Did the state of Virginia look now as she did formerly? We all knew her condition, and it was time that we should be awakened. We now saw the old commonwealth —once the first and foremost in the union—sinking lower and lower every day! Was it not time that we were tracing the cause of her decay, and if it were found to be her agricultural condition, to endeavor to revive that drooping interest? The proposition before the House was not new. It had been agitated for years. Several sessions ago, it was lost by the vote of one of the delegates from Albemarle, (Mr. Gilmer,) who thereby nearly lost his seat on this floor. The gentleman from Spottsylvania had referred to the Agricultural Societies in different parts of the state, and had supposed that like that in his county they were all declining or dead. He (Mr. K.) took pleasure in bearing his testimony to the benefits they had conferred, particularly those of Rockbridge and Albemarle (which, he said, was not dead, as the gentleman from Spottsylvania had stated,) with whose operations he was somewhat acquainted. As such good results had been compassed by county associations, he augured that farther and still more important advantages would be derived from a state institution.

Mr. K. said he would read from a valuable work which he held in his hand (the New England Farmer) to show what other states had done to promote the interests of Agriculture. In *Maine*, $70,000 was paid in one year for bounties on wheat. In *New York*, an appropriation of $120,000 was made to it. In *Indiana*, a Scientific and Agricultural College was established. In *Georgia*, a Board of Agriculture was incorporated. *Massachusetts* had encouraged it by causing an agricultural survey to be made, and by bounties on wheat, &c., *Maryland*, *Kentucky* and *Michigan* had all acted on the subject. *Maine* gave a bounty of 3 cents on cocoons, and 50 cents per pound on reeled silk; *Vermont* 10 cents, and *Pennsylvania* 20. Mr. K. then proceeded to speak of the culture of silk and the advantages which the state would derive by encouraging it. At present we imported largely from France, when we had a soil and slave labor which was peculiarly adapted to its cultivation.

Wherever, Mr. K. said, encouragement had been given by a state to agriculture, that state went ahead of its neighbors. He trusted, therefore, that gentlemen would not refuse this important interest the poor pittance of three or four hundred dollars.

Mr. Crutchfield said that the gentleman, who had just spoken, had referred to the prosperity of other states, and attributed it to the Boards of Agriculture. Now, he had often heard other gentlemen say that their prosperity was attributable to their internal improvements. This argument had been frequently used by the friends of internal improvement. Mr. C. said he was informed that there did actually exist at one time in this state a Board of Agriculture, with John Taylor at its head. That Board, thus constituted, was suffered to go down, when there was a full treasury. He would leave this fact with gentlemen to make their own application.

Mr. McRae protested against the ryder as incongruous and unfair. He trusted the House would vote down this insidious effort at the defeat of the bill. He bore his testimony to the advantages of an Agricultural Board, and of voluntary associations, as exemplified in his own county.

Mr. Strother coincided in the view, that agriculture was the most important interest in the commonwealth; yet, he contended that legislation had frequently been had indirectly for its benefit. What was the Geological Survey intended for, if not to benefit the interests of agriculture? That survey was carried on at great expense. Its object was to develope the agricultural resources of the state. Year after year, we had looked for something to grow out of it, and still the only fact that had been developed was that some oyster shells had been discovered on the Blue Ridge—a fact no doubt very interesting to the philosopher, but of no practical value to the farmer. The gentleman from Jefferson (Mr. Kennedy) had referred to the flourishing condition of Maryland and New York, and had attributed it to state encouragement of agriculture. Now he (Mr. S.) explained it thus: every man there had a direct interest in the soil (which was less in extent than ours) and is thereby induced to till it with more care. Here, a large portion of our labor has no permanent interest in the soil, and is therefore reckless as to the mode of cultivation. As to the allusion of the gentleman from Rockbridge (Mr. Leyburn) to his morus multicaulis speculations, he confessed he had suffered a little; yet he did not give full credence to the fallacy at the time so prevalent. He did not believe in the influence, which, it had been asserted, would come from the Board of Agriculture. He believed it would be as insufficient as the grand Geological Survey, from which so much was promised.

Mr. Taylor, of Loudoun, said, he had not intended to trouble the House with any remarks of his in opposition to the bill now under consideration; but many members near him expressed surprise that *he*, coming from a county distinguished for its success in agricultural pursuits, should be found in opposition to this bill. He felt it his duty to that great interest to oppose the bill now under consideration. He had been raised a farmer—a *practical* farmer, not a *book* farmer. In his opinion, it required no science and no reports from a Board of Agriculture to teach men how to handle the plough, the axe and maul. The best farmers in the world, Mr. T. said, were the plain people of Pennsylvania, who were in the constant habit of doing their own work.

Mr. Kincheloe took ground against the bill. He said the proceedings now had, in relation to the present bill, reminded him of the fact that there once existed a Board of Agriculture in the state. When that Board was established, there was no doubt the same display of eloquence in its behalf as now, and the same promises of large benefits that would result from its operation. That Board and its history might be cited as a case in point why the House should not sanction the continuance of the present. It was created with ten members, who received pay and mileage. It was continued for some years, until it was perceived that it did not answer the purposes for which it was intended, when it was abolished. Thus, the people lost about $50,000 in the experiment, before their eyes were opened. He (Mr. K.) was opposed to the bill, because he considered it would be of no practical utility or importance; yet, whilst he did oppose the measure, he declared himself to be a friend of agriculture, as the foundation and moving cause of every thing else.

Mr. Clendenin protested against the passage of the bill. It would cost 5 or $600 now, and yearly additions would be made to the expenses of the board. He therefore moved the indefinite postponement of the bill, and called for the ayes and noes on the motion.

Mr. Rives regarded the provisions of the bill, not in the light of a loan granted to agriculture, but as a *right* which that great and controlling interest might demand. Considerations of a wholly different nature from those which influenced the conduct of many gentlemen, should determine his course. He denied the dignity and consistency of the course proposed to be adopted in relation to this measure. Last winter the bill was, after a discussion, passed. Gentlemen had said, that it passed upon an understanding, that the members of the board were to receive no compensation. Had they looked to the evidence before they made the assertion? The gentleman from Spottsylvania, said it passed only on that condition. As to compensation, Mr. R. thought it was merely a matter which had been omitted in the bill establishing the board. The members had met and deliberated. Gentlemen declared they had done nothing. True—but, asked Mr. R., had they not taken incipient steps for obtaining a consummation which would redound to the honor and interest of the whole commonwealth?

Mr. R. then spoke of the impropriety and inconsistency of the course proposed to be adopted, by the ryder of the gentleman from Rappahannock. It was proposed to tell the members "you have done nothing—you have been of no service—still, we will pay and discharge you." Was it wise, dignified, or prudent to say this to those gentlemen; to destroy the board, and yet pay them a few dollars and cents? As honorable and high-minded men, would they receive the compensation tendered under such circumstances? Mr. R. asked gentlemen to pause before they abolished this board, and before they came to the conclusion that it could do no good.

Mr. McIlhaney said, he was unused to public speaking, but was sincerely devoted to the agricultural interest of the state. No man in the house excelled him in the zeal which he felt, and was ever ready to manifest, by his practice, for the *bone and sinew* of his country. He was emphatically a farmer in all his notions and feelings. He had been partly brought up to the plough. With all the care and attention of which he was capable, he had listened to the arguments and views of those who had advocated this measure. He had seen gentlemen of the bar, rise and theorise on farming with all their strength. Now, he could say, as to those gentlemen, that, if they expected their sons to be benefited by the theories of a board of agriculture, they were very much mistaken.

But, said Mr. M., the House has been told by the gentleman from Jefferson (Mr. Kennedy,) a man who was very near to his heart, that much good had resulted to the cause of agriculture by boards established in other states. He referred to Pennsylvania. He would accompany the gentleman in his investigations in that quarter, for he had visited that state and spent some time there;

it was to improve his knowledge and enlarge his views by inspecting the system of cultivation pursued by the farmers in that country. In that great and fertile valley extending from Philadelphia to Lancaster and Columbia, and thence to Little York, whom did he find to be the best and most successful farmers? who possessed the most highly improved lands, and most remarkable for economy? Those who have been brought up to the plough handle; those who trod their own soil, the honest, plain-spoken, hard working Germans, who never saw the printed report of an agricultural board. They taught me more in a day or two, than a board of agriculture could in a year. The German farmer affords an instructive example to any one who would seek to know how to carry on a well-cultivated farm—and this truth is strongly illustrated in the county which he had the honor in part to represent. Mr. M. said his people were economical in their principles and habits, and had clearly intimated to him to study economy in his votes. So long as he retained his senses, and knew what he was doing, he meant to do his duty, and carry out their wishes. If the scheme before the House was a good one, he would vote for it; but he did not so think. It might only cost $500 now, but hereafter, it would cost thousands without an equivalent. This small sum was the beginning—improvements of the scheme would be thought of, and more money demanded to carry it out. He should, therefore, vote against the bill, and hoped, if the learned lawyers who advocated it, wished their sons to acquire agricultural knowledge, they would encourage papers, friendly to the diffusion of information upon this subject, and bring them up to a practical knowledge of the plough and the scythe.

The question was then taken on the engrossment of the ryder, and decided in the negative.

Mr. Scott of Fauquier then addressed the House briefly, in support of the bill—after which it was passed—ayes 90, noes 34.

[The bill, as passed, was before published at page 138 of this volume of the Farmers' Register.—Ed. F. R.]

REMARKS ON THE LEGISLATIVE DEBATE ON THE BOARD OF AGRICULTURE.

We have reluctantly given the space it occupies to the debate on the bill for paying the Board of Agriculture. *Reluctantly*, we say, because, though the debate forms a large part of all the legislation of Virginia for the benefit of agriculture, and therefore has a right to a place in the Farmers' Register, we are really *ashamed* for Virginia, that the decision should turn on such facts and such arguments as are there displayed. We are not objecting to the course of any member of the legislature for opposing the establishment of a Board of Agriculture, nor for his voting against the last bill, because of such general opposition. Our most intimate associations were with some members who have been throughout thus opposed to the establishment, and to all legislation thereon; and in all our intercourse, we never uttered to one of them a word, in the hope of removing their objections, and still less would we have thought of blaming their decision. We can very well appreciate the objections of such opponents, when even *we* almost despair of any important service being rendered by the Board, discountenanced as it has been from the beginning, and treated with suspicion and contempt by the legislature; and without promise, or any yet visible appearance, of designed support and aiding labors from the agricultural class. It requires but little stretch of wisdom to infer, and to predict, that if left to rely upon their own exertions only, without aid and without sympathy from their fellow agriculturists, all the zeal and labors of mind and body of the members of the board will result in nothing, compared to its great objects, and to what might be the results of such an institution properly aided and sustained.

We object not, therefore, to the mere opposition of legislators to the bill, but to the manner of their opposition, and the ignorant flippancy exhibited in the debate. Mr. Strother condemns and ridicules the members, because in their first and only session they had communicated no important agricultural information: and he speaks contemptuously of them, because they so soon "wanted their pay." Now we should be glad to be informed *what* information could possibly have been expected from a board just met and organized, and which merely remained in session long enough to digest a plan for future operations, if enabled to act at all, by the aid of the legislature and the farmers of the country? If, instead of this course, the members of the Board had proceeded to put forth a report of their individual agricultural opinions, and had remained long enough in session to digest, write out, and submit the elaborate report to the legislature, would not Mr. Strother have been among the first and loudest to prefer against them the well-founded charges of foolish presumption, and of making a useless demand on the treasury, by such length of session? As to "their pay," it is very true that this subject occupied part of their report, and with good reason. Every man must know that there never could have been a second meeting of the Board, if the members were *again* expected to come, at their own expense, from the most remote regions of the state. It was therefore the duty of the Board frankly to state the existence of an obstacle which, if remaining, would certainly prevent any useful or continued action of the body; and which, if not removed, would render perfectly futile all efforts to carry into effect any plan of operations which might be prepared. It would have been but a ridiculous farce to digest and to start a general plan of procedure,

which could not by possibility proceed to fulfilment. And the men who submitted to accept the appointments, under such discouraging circumstances, (independent of subjecting themselves to the ridicule and contempt of such as Mr. Strother,) have already made, and are prepared to make sacrifices for the public good, of which Mr. Strother probably has no conception of the possibility.

Mr. Strother further charged, (without the least foundation of fact,) that the Board "informed us that they had turned their attention to the geology of the state;" and in a subsequent speech he charges as given to the encouragement of agriculture, all the large sum that has been thrown away on the geological survey of the state. He cannot think much worse of the manner of that expenditure and its results than we do; but it is utterly unfounded to charge it to agriculture. It has been emphatically *a job*—such as legislative bodies are easily persuaded by plausible and self-interested lobby members to allow for private benefit, under pretences of subserving the public good—and which, (the geological survey,) has been of not the slightest benefit to agriculture, and very little to any other *public* interest. Mr. Strother is welcome to refuse even to give the present estimated expenditure of $500 a-year to aid agricultural improvement; but we protest against his claiming that some $40,000 have been already applied to that object, because so much has been spent in the costly humbug termed a geological survey. If given to that bottomless pit, the James River canal, it would have been more profitably expended.

Mr. Crutchfield informs us that a Board of Agriculture formerly existed in this state, with John Taylor of Caroline at its head, and which, proving worthless, was suffered to go down. And Mr. Kincheloe adds to this newly discovered piece of history of agriculture in Virginia, that in the few years it continued in worthless (and since forgotten) existence, this Board cost, in pay and mileage of its members, some $50,000 to the people "before their eyes were opened." No correction or reply was offered to these statements, by any member, and therefore we presume that they were admitted as true. It is, however, the first intimation that we have had of such occurrences; and however hazardous it may be to assert a negative, and to deny the existence of legislative acts affirmed by legislators in debate, we will presume to express our confident belief that there is not one word of truth in the whole statement—that there never has been before a Board of Agriculture established by the state—and of course that John Taylor was not at its head—and that no such cost as $50,000, nor any other cost, was caused by any such establishment. Though not much conversant with laws or legislative proceedings, and therefore we may well be ignorant of many such matters, we remember some facts which we presume served for the entire material of which this old and forgotten "Board of Agriculture" was manufactured. There was once in existence an Agricultural Society of Virginia, over which John Taylor presided—which society asked and *was refused* legislative aid and bounty, for the improvement of agriculture. These facts, we infer, are the true original "something as black as a crow," which became "the three black crows," thrown up by Mr. Crutchfield and Mr. Kincheloe before the House of Delegates.

The results of all the labors and efforts of the Board of Agriculture may indeed prove to be as worthless, and their procedure as profitless to agriculture, and even as contemptible, as Mr. Strother has endeavored to make out. But whether so or otherwise, the Board, or its working members, will not the less have labored much more than is to be recompensed by "their pay." The full payment for the session of six working days, and travelling expenses, of the member who writes these comments, amounted (as understood from the law, for it has not been drawn,) to $22. And he is very confident that he has performed more labor than did most of the members of the legislature in six weeks of *their* session—and that his labors were as little directed by the consideration of the *per diem* allowance as those of any member of the legislature, whether voting for or against the repeal of the 90 days' limitation or "starvation law," of the late session.—Ed. F. R.

SHAD FISHERIES.

From the Philadelphia Ledger.

In your paper of the 31st March, you remark that "a large number of fishermen left the city yesterday for fishing, with shore nets. Shad may be expected in abundance, and the price greatly reduced. They are not allowed to fish for them (shad) but with gill nets, till the 1st of April."

In this latter clause you are in error. The laws for regulating the shad fisheries do not specify the time to begin operations with either description of seines, but do fix the period at which they shall cease, viz., on the 5th day of June.

The gill seines are, at this early stage of the season, fishing below where the Delaware and Pennsylvania line strikes the shore, and are of course out of the concurrent jurisdiction of Pennsylvania and New Jersey, and not amenable to the laws regulating their respective fisheries.

It is by thus assembling in the lower part of our river, to the number of several hundred nets, varying in length from fifty to near three hundred fathoms each, stretched directly across, and drifting with the current, breaking up and dispersing the shoals of shad, and confining them to the salt or brackish water, where they are compelled to

deposite their eggs, which are of course lost, instead of being allowed to reach the fresh waters whither their instinct directs them, that the great scarcity of shad, of late years, is wholly attributable. In the Connecticut and Delaware rivers, in the ratio of the increase of gill nets, the shad have decreased. On the Potomac river, on the other hand, where the gill nets are not allowed, but where the shore seines, in some instances, are nearly a thousand fathoms long, and where they commence fishing as early as they please, and fish as long as it is profitable, (Sundays *not* excepted,) the shad are as abundant as ever. Indeed they were never caught in greater numbers there than last spring. Such too was the case in the Delaware, until the gill nets were so greatly multiplied. Before this description of net was introduced here, the shore seines, then more numerous than now, supplied our city and the country adjacent to the river with abundance of shad, at an average price of from six to eight dollars the hundred—of late it has attained to twenty dollars the hundred.

That the gill seines do cause the shad to leave our river, may be proved by the fact, (related to me by a respectable and inteiligent old fisherman from Egg Harbor,) that a few years ago the shad entered our bay in great numbers; the gill nets met them early and far down, and took them in great quantities—when suddenly they became scarce, but in a very short time after made their appearance in the inlets along the Jersey coast. His conviction was, at that time, that, meeting with such obstructions, they abandoned the Delaware for other waters. This conclusion is borne out by a fact related to me only a few days since, by a gentleman once largely interested in the shad fishery, that in the early part of last spring, the shad ascended this river in considerable numbers, to where the gill seines obstructed the channel, and were taken in great numbers by them; that they soon, however, commenced a retrograde movement, the gill seines keeping pace with them. The inference is clear that they *too* left our river, inasmuch as but comparatively few reached the shore fisheries immediately above. Indeed, some of the latter, hitherto valuable, did not defray expenses.

So far is it from being probable that the price of shad will be "greatly reduced," the experience of every succeeding season, of late years, shows that it has risen with the decrease of the shad. Indeed, the predictions made by experienced fishermen, when the gill nets were first introduced, that shad, in consequence of them, would soon become as scarce in the Delaware as salmon were in the Connecticut river, seem likely to be verified.

S.

CAUSE OF PHYSICAL DEGENERACY.

From the Maine Farmer.

The question was asked in the Farmer a long time since, "What are the causes of the deteriotion of the human race for the last fifty years in America?" I have never seen it answered to my entire satisfaction. Undoubtedly a number of things have or might have had a bearing on the subject, but if animal life consists in the effect of stimuli operating on what may be stimulated, then it seems that an exact proportion of stimuli to excitement, excitability, or what may be stimulated, would be perfect health, (if such a thing ever was.) I know that too much stimulating food and drink, if the above principles are sound, would produce just what we see has taken place. Our diet has been too much animal food, and particularly that which is oily. Destroy digestion in any animal and you belittle him. The use of tea and coffee in the room of milk, and the several kinds of mixtures that used to be made from milk, is another cause. Provoking the appetite by the modern art of cooking with too great a variety, to eat too much, is another cause. As I have before said, destroy digestion, and you belittle any race. Hard grain given to young colts has done it, and produced lasting disease through life. Very high keep in pigs, and a confined life, will and has done it in that race. Rum will destroy the growth of a puppy—and the deleterious effects of ardent spirits upon the human system are, alas! too plainly apparent. I will also mention a lack of exercise in the open air, among the causes of degeneracy. This is best obtained by *actual labor*.

In order to renew our race, let us return to the diet, exercise and habits of our forefathers of the revolution.

I do not pretend that I have done the subject justice. I merely submit the above as a few, what I call, common sense thoughts.

NOT A PHYSICIAN, BUT AN
OLD-FASHIONED FARMER.

URINE.

(From Squarey's Treatise on Agricultural Chemistry.)

"When it is considered," says Liebig, "that with every pint of urine, a pound of wheat might be produced; the indifference with which this liquid excrement has been regarded is quite incomprehensible."

We can here only join in expressing our surprise at such neglect; but we would at the same time fain hope that such neglect has arisen entirely from ignorance of its value, and in the zealous endeavors that are now making by agriculturists at large, and the zeal, energy, and ability that is now displayed, we may fairly anticipate a juster appreciation of this manure for the future.

That we do not overrate the value of this manure, may be proved from the following results of the analysis of 100 parts of wheat manured in different ways, and which places human urine in the very first place as to value.

We have before stated that the weight and value of wheat as an article of food, depends on the quantity of gluten it contains, and this fact admitted, no other argument is required to convince us of the superiority of urine as a manure:*

100 parts of wheat manured with

	Gluten.	Starch.
Human urine (dried) yielded	35.1	39.1
Bullock's blood (dried)	34.2	41.3
Human fæces (dried)	33.1	41.4
Sheep's dung	22.9	42.8
Pigeon's dung	12.2	63.2
Cow's dung	12.0	63.3
Vegetable Humus	9.6	55.9
The same soil not manured	9.2	66.7

* Analysis of Hermbstoedt, quoted by Professor Dauberry.

We have elsewhere endeavored to show, that all excrement partakes of the nature of the food; that if food, consisting almost wholly of nitrogen, is consumed, that such excrement will principally consist of the nitrogen not required to supply the waste of the body. That if food principally consists of substances in which carbon predominates, that the matter voided as excrement neither is nor can be so rich in nitrogen as in the preceding case: the rule holds good throughout all creation; and therefore, as man is a carnivorous animal, and lives in great measure on the flesh of animals, a substance almost entirely composed of nitrogen, human urine is much richer in this substance, nitrogen, than in animals living exclusively on vegetables. The analysis of these matters accordingly proves that human urine contains four times more fertilizing matter than the urine of horses, cows, and sheep.

In all the remarks then that follow, we must be considered as speaking of human urine; but the same arguments will apply to the urine of all animals, only in lesser proportion.

And it must be again repeated that the liquid excrement of all animals is infinitely to be preferred as a fertilizer to the solid excrement, the urine in all cases containing all the soluble salts which are thrown off from the body as waste matter; such as the ammoniacal salts, the phosphates or soda, potash, and magnesia, the substances which are now recognized as constituting the ingredients of all kinds of grain, and which are essential both to their growth and developement, and for supplying the nutritive matter of the grain.

Berzelius gives, as the contents of one thousand parts of human urine in his elaborate analysis of the fluids,

	Parts.
Urea	30
Lactate of ammonia and animal matter	17¼
Uric acid	1
Sulphate of potash	3¾
Sulphate of soda	3¾
Phosphate of soda	3
Phosphate of ammonia	1½
Chloride of sodium	4½
Muriate of ammonia	1½
Phosphate of magnesia and lime	1
Water, mucus, and silex	933

"If from the above analysis, we take the urea, lactate of ammonia, uric acid, the phosphate and muriate of ammonia, one per cent. of solid matter remains, consisting of ammoniacal salts, which must possess the same action, whether they are brought on a field dissolved in water or urine," Hence the powerful influence of urine must consist in its ammoniacal salts. Now, when urine is allowed spontaneously to putrefy, one portion of the ammonia unites with the lactic acid to form lactate of ammonia, and another becomes volatile in the state of carbonate of ammonia.

The formation of this carbonate of ammonia entirely alters the state of the urine, rendering it an alkali, instead of an acid, which it is in its natural state; and this explains why putrefied urine is to be preferred as a manure to urine in its fresh state. Now the great object is to fix this carbonate of ammonia, or at all events the ammonia, in the soil.

If the urine is applied as a manure in this state, that is, with the lactate and carbonate of ammonia in solution; the latter salt, from being volatile, will evaporate with the watery parts of the fluid; and the loss which would accrue from this mode of using it, would amount to nearly one-half of the weight of the urine employed. So that, if by any means we can fix the ammonia, that is, deprive it of its power to fly off with the evaporation of the watery parts of the urine, we shall increase its action twofold. This object may be effected in a variety of ways. If a field is strewed with fresh burnt gypsum (sulphate of lime) and then the putrefied urine be applied on its surface, the gypsum will absorb and decompose the carbonate of ammonia, and the carbonic acid gas thus disengaged, will unite with the lime to form carbonate of lime, and the sulphuric acid of the lime will unite with the ammonia to form sulphate of ammonia and this salt will remain in the soil and not be volatilized.

But a simpler way still is to mix the gypsum with the putrefied urine, and thus effect the double decomposition above described before distributing it on the soil.

The quantity necessary will of course depend on the quantity of carbonate of ammonia the urine may contain, and this not only varies with every stage of putrefaction, but depends also on the way in which it has been kept; and again on the quality of the urine itself, no very definite quantity therefore can be named. But an easy way of knowing how much gypsum to put to a certain quantity of urine is to add it constantly at intervals of a few hours (taking care to stir the mixture well occasionally) as long as any volatile smell, similar to hartshorn, escapes, the absence of which will be a sure test that the ammonia has lost its volatile property, and has become, to use a chemical and expressive term, fixed.

Chloride of lime may be used for the like purpose, but being more expensive than the gypsum, it would not of course be resorted to.

Dried peat, tanners' bark, sawdust, turf and other similar substances, may be also used for this purpose, but the gypsum is decidedly preferable.

Sulphuric acid, the oil of vitriol of commerce, may also be advantageously used to fix this salt, and to do so, nothing more is necessary than to mix a sufficient quantity of this acid with the putrefied urine, until almost all effervescence ceases, keeping it well stirred during the whole of the time, and taking care not to add an excess of acid. In this case the ammonia unites at once with the sulphuric acid, to form the sulphate of ammonia; and the carbon being disengaged, escapes in the state of a gas.

Other means might be used to effect the same results as we have here demonstrated; but it is needless to specify them, as those we have already detailed combine great facility as well as extreme cheapness.

Having thus specified the change that takes place in the state of urine, the best manner for converting the ammonia for the purpose of agriculture, we shall suggest the best means of practically using this manure on a farm.

The first thing necessary is to procure a supply of urine. But if due care is used to save all that is now wasted, no farm need be in want of it.

The supply being obtained, it should be placed in large casks or tanks under cover, until the vo-

latile smell of the ammonia indicates that decomposition has taken place. When this occurs, it may be either poured over a heap of compost, consisting of coal ashes, charcoal or gypsum, in any proportions that are the most conveniently obtained, and then allowed to dry by frequently turning the heap. Care being taken, that if any volatile smell occurs, during this process of drying, that more gypsum be at once added. The volatile ammonia will in this operation be absorbed by the gypsum, and converted into a sulphate of ammonia, and other parts will be absorbed in the gaseous state by the charcoal and the ashes; but all will at once be yielded up to the first moisture that may come in contact with the heap; and therefore, it may be very properly classed amongst those fertilizers which act as a stimulus to the plant. We would, therefore, reasoning from analogy, suggest the use of this dried compost, as an excellent substitute for bones in the drill in sowing turnips. And we are further confirmed in this opinion, from the fact, that the new manure, the urate, only lately introduced, and which is presumed to be prepared somewhat in this way, has been found to answer admirably for the purpose intended. The addition, however, of a phosphate of lime, would increase its value in this respect, and render it undoubtedly more valuable than bones for this purpose.

Another compost heap, which would answer admirably for any purpose almost for which a manure can be required, that is, either as a stimulant for turnips, as a pabulum for wheat, or white crops —or, again, as a top-dressing for either of the above, or for grass—may be readily formed by mixing long stable litter, in which decay has already commenced, with the burnt ashes of vegetables or wood, in somewhat indefinite portions; taking care, however, that the litter should predominate, and then pouring over the heap daily a portion of the putrid urine, and stirring the mass well up together.

In this heap the ammonia of the urine would be decomposed; but the nitrogen, the vivifying principle of the ammonia, would unite with the alkaline matter, the soda or potash of the burnt vegetable ashes, to form nitrate of potash or soda: the hydrogen, the other constituent of ammonia, being given off.

After what has already been said about the utility of these salts as fertilizers, it will be needless to add more here, than earnestly to recommend every agriculturist to adopt these simple means for the production of two manures, which in value to the farmer cannot be surpassed—both for the facility and economy with which they may be prepared, and which would by their fertilizing properties confer a benefit not only on the farmer, but on the community at large.

It may be urged as an objection, that in many localities, far distant from towns and cities, this manure could not be obtained in sufficient quantities to supply the place of other substances more readily obtained. To this objection we would beg to suggest, that if ever a demand for this article exists, means will be taken to secure a supply; and, that in such a case as above supposed, the farmer's wagon would be enabled to load back from the town or market where their produce must eventually be consumed, with this matter. And further, they may commence with the supply that is always to be had to some extent on their own farms, and thus verify the results here predicted.

We will only add, that the urine of one man, taken at its lowest calculation, will produce in one year, a sufficient supply of nitrogen for the formation of 800 pounds of wheat, or 900 pounds of barley; a fact of sufficient importance, it is hoped, to induce a trial at least—and this trial fairly made, we have no doubt of the result.

Indeed, if all the human excrement, now worse than wasted, were applied to the purposes of agriculture, animal manure might be entirely dispensed with. But if we look at the subject on an extended scale, and see the thousands of acres now barely cultivated at all, but all of which only require manure to be applied to them, to enable them to yield abundant crops; and if we reflect on the benefits all must derive from such an increase to the real wealth of the country, as the cultivation of these lands would induce; and further, that the increased means thus afforded, would as certainly induce an increased population, which again in their turn, acting fully up to this system, would again prove another source of wealth and strength to the community—we may be enabled to estimate in some slight measure, the order and arrangement that exists in nature, for the support of all her creatures; and that it is the neglect of those means, which providence in its wisdom has placed at the service of man, and not any imperfection in the grand scheme of the creation, which has induced the impious belief by some, that a redundant population may be a curse instead of a blessing.

But to return more immediately to our subject. Enough has been said to show that ample means exist for bringing all the waste lands gradually into cultivation; that we have the power, if we have the inclination, to do so. And the circumstances of an increase, and rapidly increasing population, may compel a much more attentive consideration, than this subject has hitherto received, and one which eventually must lead to the benefit of all classes concerned.

So much for human urine. The urine of animals, as previously stated, from the nature of their food, contains much less nitrogen than that of man; but is equally, and in many cases, much more rich in the saline properties it contains, such as the phosphates of magnesia, and the salts of potash and soda. They are, therefore, by no means to be neglected, and indeed all the remarks appended to the subject of human urine apply here only with lesser force. We would, however, recommend, that all stables, farm-yards, sheds and other places where cattle are kept, should be so arranged, as for the urine to be saved, and applied in the manner we have before described.

Connected with this subject it may here be stated, that the strong volatile smell, which is almost overpowering, when entering a close confined stable, where many horses have been shut up for the night, arises entirely from the volatilizing of ammonia in the urine.

A very simple, and at the same time a very profitable way, of correcting this injurious atmosphere, is to strew the stable with gypsum, which would absorb the ammonia at once as it is formed, and prevent the presence of this gas in the atmosphere. Such an arrangement, besides being pro-

fitable, as one source of accumulating ammonia, would also act beneficially on the horses so confined, as there can be no doubt, that breathing such an atmosphere constantly for some hours together, induces a highly excited temperament, which leads to, or at all events very much increases, any local inflammatory action, and renders the cure of such a malady both difficult and uncertain.

These remarks, however, do not go to the length of suggesting the use of gypsum as a cure for such a stable, it is only a means of absorbing the obnoxious principle and turning it to account; but ventilation, to a considerable extent, is the only cure and the best.

Of the relative value of human urine, when compared with other animal matters, it is calculated by Macaire, that 100 parts of human urine are equal, in their fertilizing power, to 1300 parts of the fresh dung of the horse, or 600 of those of the cow. Nothing more therefore can be said in favor of this manure; it must now be left to those who have the means of applying and testing its real value.

In speaking of nitrogen we have fully explained how ammonia acts as the pabulum of plants, but we will here again shortly repeat it.

Ammonia is composed of nitrogen and hydrogen. Now, when the ammonia, in a state of solution, is absorbed by the spongelets of the roots, decomposition takes place, the nitrogen is assimilated to form the gluten of the seed, and the hydrogen either unites with carbon, to form the essential or fixed oil of the plant, or is evaporated through the leaves as useless matter.

That such is the effect of ammonia or nitrogen, applied under any circumstances, in which the salt is soluble, can be easily demonstrated, by applying it to any crop, when it will speedily assume a dark green color and luxuriant appearance, which is the peculiar effect of the nitrogen alone, and which is forcibly illustrated in the dark green circles, popularly called fairy rings, which exist on the downs, and which owe their dark color entirely to the mushroom or fungus spawn, existing under the surface, and which spawn consists almost wholly of nitrogen, and communicates its property to the grass growing above.

The specific action of nitrogen also, by endowing the plant with greater energy, enables it to assimilate more carbon from the atmosphere, and thus the addition of this manure, which is in every respect an essential to plants, gives it a greater power of assimilating another substance of almost equal importance as itself.

In concluding our notice of this manure we can only repeat that the liquid and solid excrement of man used together, and prepared in the way we have described, forms from its combination of ammonial salts, with the phosphates of magnesia and soda, the most valuable compound that can be devised, and its extensive use will confer a double benefit to the farmer and to the public, as well by the removal of matter, which is now only considered as a nuisanse, as by increasing the produce of the soil.

PRUNING FRUIT TREES.

From the Maine Cultivator.

Those who have fruit trees that require trimming, would do well to attend to it now. It has been clearly ascertained, I think, that the practice of pruning apple, pear, and other fruit trees at this season of the year, is much more judicious than that of pruning in the fall or winter. Perhaps there may be some whose experience would seem to point to the opposite course; and it may even be, that in certain instances, the results have been far less favorable than was anticipated.

But as a general thing, I think there can be no doubt, that wounds, caused by the excision of limbs, heal much more rapidly, and are far less detrimental to the health of the tree than those inflicted at any other time.

The *rationale* of this theory will be obvious to every one who reflects upon the subject, and need not here be explained at length. Those who have fruit trees infected with the wart, or black excrescences which have of late proved so fatal to our best fruit trees, in many sections of New England, especially the cherry and damson, would do well to look to them. There is now no ground to doubt the origin of this disease. It is caused, indubitably, by the minute perforations occasioned by vernal operations of a certain fly which seeks the soft and yielding bark as a *nidus* for their future young.

The *larvæ* of this insect being deposited in the cuticle, lies there irritating the delicate vessels, and thus occasions the exudation of the sap which originates the disease. I remember having seen an able article some years since in the Yankee Farmer upon this subject, from the Hon. Rufus M'Intire of Parsonsfield, in which it was recommended, that all limbs infected with this disease be immediately cut out. The writer represented that he had thus entirely overcome it, and that no doubt need be entertained as to its efficiency, or fears for the tree.

There are few subjects connected with the farming art on which more has been said and written, than upon this. And yet there are thousands whose trees are now suffering, and who are endeavoring to regain their regeneration by the application of remedies; the legitimate effects of which are decidedly adverse to the securement of their aim. W.

Windham, April, 1842.

The opinion of our correspondent, that this is the season of the year for general pruning, although of ancient date, is nevertheless a good deal questioned hereabouts.

Except in grafting or heading down, which ought to be done "about now," good orchardists are getting in the way, and we think judiciously, of pruning in the longest days in the year, say in June, or July.

Wounds in trees, caused either by the excision of limbs, or in the bark, heal up more readily in June or July, according to our observation, than they do, if inflicted during the flow of the sap: and the sooner this is effected after the excision, the better it must be for the tree. He who has a proper regard for the thrifty growth and life of trees, will avoid doing any thing to prevent the annual formation of the viscid substance which covers the tree beneath the bark, as this layer

is indispensable to their vigor and health. This substance is formed in the spring or early summer, by the free and regular circulation of the sap, and to trim trees before this layer is formed is thought to be very deleterious to their growth.—*Ed. Maine Cultivator.*

LIME.

From Sinclair's Husbandry.

There is perhaps no country in Europe, where calcined lime is used to so great an extent, and in such quantities, as in the more improved and improving districts of Scotland. This may be partly owing to the total absence of chalk, which abounds in so many parts of England, and which renders calcined lime less necessary there; but it is principally to be attributed to the great benefit that has been derived from its use. In bringing in new or maiden soils, the use of lime is found to be so essential, that little good could be done without it. Its first application, in particular, gives a degree of permanent fertility to the soil, which can be imparted by no other manure. Its effects, indeed, are hardly to be credited, but their correctness cannot be disputed. Maiden soils, in Lammermuir, of a tolerable quality, will, with the force of sheeps' dung, or other animal manures, produce a middling crop of oats, or rye; but the richest animal dung does not enable them to bring any other grain to maturity. Peas, barley, or wheat, will set out with every appearance of success; but when the peas are in bloom, and the other grains are putting forth the ear, they proceed no farther, and dwindle away in fruitless abortion*. The same soils, after getting a sufficient quantity of lime, will produce every species of grain, and in good seasons bring them to maturity, in all future times, always supposing the ground to be under proper culture, and the climate adapted to the crop. This fact proves, that oats and rye require less calcareous matter than what is necessary for other grains; that lime acts as an alterative, as well as an active medicine, and that the defects in the constitution of the soil are cured, even after the stimulant and fertilizing effects of the lime have long ceased to operate. Lime is also peculiarly beneficial in improving muirish soils, by making them produce good herbage, where nothing but heath and other unpalatable grasses grew formerly. The expense of this article in Aberdeenshire is stated to be enormous, very little of it being produced in that country; yet lime is there considered to be absolutely necessary, and, indeed, the foundation of all substantial improvements.† It is supposed, however, not to be so useful on the sea-shore, as in the more inland districts, from the soil being perhaps mixed with sea-shells.

The importance of lime as a manure is strikingly exemplified by the following information from Mr. Walker of Mellendean: He entered into the possession of that farm twenty-five years ago, and then gave the whole farm, (with the exception of a few acres of the *richest soil* in different fields, which had for ages been manured as infield,) a good dose of lime. From the newly-limed land, his returns were fully equal to his expectations, and greatly superior to those from the richest spots that had received no lime. Being very desirous to ascertain how long the limed land would maintain its superiority, he kept both the limed and unlimed under the same management in every respect, during his first lease of twenty-one years; and he can affirm, that at the end of that period, his crops upon the limed land were equally good, and as much superior to those of the unlimed land, as they were at the commencement thereof. Having got a new lease of that farm, he proposes laying lime upon every spot of ground that was not limed formerly, being convinced that he has been a considerable loser by his experiment. How long therefore the effects of lime may last, he will not take upon himself to foresee; but he can safely say, that there is land upon his brother's property at Wooden, that was limed by his farther upwards of thirty years ago, where the effects of the lime, upon every crop, are still as apparent as when it was first laid on the land.

It is proposed, in discussing this subject, very shortly to explain the following particulars: 1. The soils to which lime is applicable; 2. The distance from which it has been carried; 3. The quantity used; 4. The best mode of slacking; 5. The common modes of application; 6. The plan of top-dressing the surface; 7. The price; 8. The use of pounded limestone; and, 9. The causes which may occasion its failure.

1. This manure is certainly well calculated for clay lands. Some recommend laying on a certain quantity of it, to the amount of 20 bolls of shells, or 120 bushels, to the Scotch, or 96 to the English acre, and as hot as possible, every time the land is fallowed. This plan, however, is objected to from respectable authority; and it is contended, that so small a quantity of lime shells is quite unfit for stimulating any kind of soil, except where it is of a dry muirish nature, and not formerly limed. To lime land every time it is in fallow, seems unnecessary, more especially if a sufficient quantity were applied in the first instance.* From 60 to 70 barley bolls *per* Scotch acre, or from 390 to 420 bushels *per* Scotch, that is, from 288 to 356 bushels *per* English acre, are quantities frequently given in East Lothian. In regard to loams, if they are in good condition, and in good heart, perhaps liming once in the course of two rotations will be sufficient.† It is a rule, however, in regard to the application of lime, and other calcare-

---

* Marl, although containing calcareous matter, is not so effective. It will produce oats, barley, and early peas in abundance, and in some situations will also produce wheat, when the season is favorable; but wheat crops cannot be depended upon from marl alone.

† Communication from Mr. Barclay, Mill of Knockleith. It is observed, that lime has sometimes been withheld both from low lands after fallow, and from hilly lands after turnips; but in all these cases, with an evident loss to the occupant, by a decrease of produce throughout the whole course.

* Mr. John Shirreff remarks, that to specify a quantity for all lands is impossible, so much depends upon the depth and quality of the soil; also on the quantity of calcareous matter, either previously applied, or originally in the soil.

† Communication from George Paterson, Esq. of Castle-Huntly.

ous manures, that they should only be applied to land in a dry state, and well drained.

2. It is astonishing the distance from which lime is carried in some parts of Scotland. Mr. Blackie of Holydean, in Roxburghshire, drives it twenty-two miles, and the carriage, when hired is 7*s*. 6*d*. *per* boll of shells. In the parish of Moffat, where of late considerable improvements have been carried on, and corn, turnips, and clover, raised in great perfection, 1000 feet above the level of the sea, the lime is carried from Douglas, at twenty-seven and thirty miles distance. It is sometimes carried on the borders, but in no great quantity, about thirty, or even thirty-two miles;* and in Aberdeenshire, it is driven that distance inland, after being imported from Sunderland.

3. The quantity used varies much. It is evident that strong deep soils require a greater quantity than those which are light and shallow. Baron Hepburn is of opinion, that it should be applied frequently, and in small quantities at a time, especially on gravelly-bottomed loams, which are apt to become too open and pliable by an over dose of lime; by following this practice, he finds his crops wonderfully improved, both in regard to quantity and quality. Mr. Robertson of Ladykirk states, that he has never seen lime used in too great a quantity, if the land is judiciously cropped; if otherwise, it will ultimately hurt the soil. He has laid on no less a quantity than 100 bolls of shells, 4 Winchester bushels each, *per* English acre, and frequently with much success. On dry fresh land a less quantity will do. Mr. Blackie of Holydean considers 16 bolls of shells, on such land, a sufficient dressing. Dr. Coventry is of opinion, that in general, about 6 tons of unslacked or newly-burnt lime, of ninety or ninety-five *per cent.* of purity, may be sufficient for the statute acre of land that has never been limed; but if the lime be impure, a greater proportion will be requisite. Several intelligent farmers are of opinion, that not less than 60 or 70 bolls of lime shells *per* acre, should be laid on a strong clay soil, and that this quantity, with judicious cropping, will be sufficient for a lease of 19 or 21 years.

The information transmitted to me by Mr. Walker of Mellendean upon this subject, is of peculiar importance, as he has limed perhaps more land than any individual in the whole island, and in the course of thirty years has tried various experiments in regard to the quantity that should be applied *per* acre. On newly broken-up land from old turf, he has laid on from 20 and 25 to 40 and 45 bolls of shells, of 4 Winchester bushels each, *per* English acre. On light and thin (outfield) soils, the crop on that part of the field that was limed at the rate of 20 and 25 bolls *per* acre, was as rough, and appeared equally good, with the crop on the land that had received 40 bolls *per* acre; but when it came to be thrashed out, the grain was found very inferior in quantity, and still more so in quality. Upon clay soils, the effects of the lime, where a small quantity was laid, were hardly discernible; while that part of the field that received 40 and 45 bolls produced an abundant crop. Finding the produce of the land that was limed with a small quantity so very inferior, he laid on, (when the land came to be re-fallowed), 20 or 25 bolls more, the effects of which were never perceptible. He is therefore decidedly of opinion, that every kind of soil should have a good dose at once, in which case he considers no repetition to be necessary for a long time after; but if repeated at all, the second liming should be considerably greater than the first, which seems to be the general opinion of the Scotch farmers. As to repeated liming in small quantities Mr. Walker is convinced, that whatever is laid out in that way, after the first dose, is so much money thrown away. He can give no stronger proof of his conviction in that respect, than his practice upon the farm of Rutherford. He entered to that farm in June 1808, and since that time he has gone over about *eight hundred and fifty acres*; and though a great part of it consists of a light dry soil, and the lime has to be carried twenty-four or twenty-five miles, consequently at a great expense, yet on no part of the farm has he laid less than 40 bolls, of shells, or 240 Winchester bushels *per* English acre, and on many places fully 50 bolls. Nothing, in his opinion, assimilates the produce of outfield, to that of infield land so much, as a good dose of lime laid on at once. The consequence of this liming has been, the most productive crops, of every description, to be seen in all that neighborhood.

Mr. Aitchison of Clements Wells also has found that lime answers every purpose he could wish, in promoting the improvement of his estate in Peebles-shire, where the climate is cold and moist. He began to improve that property in 1806, and in October 1811 he had laid on it, 10,386 bolls, or 62,316 Winchester bushels. His ridges are 18 feet broad; and according to the quantity he wishes to put on *per* acre, his overseer has the following table to conduct the operation.

If it is proposed to lay on 25 bolls *per* acre, betwixt each heap, of one firlot each, there ought to be a distance of - - - - - 30½ feet.

If 30 bolls,	- - - - -	25¼
35 do.	- - - - -	22
40 do.	- - - - -	19
45 do.	- - - - -	17

And in the same proportion as high as 50 bolls. He never puts on less than 25 bolls, or 150 bushels of shells, *per* Scotch, (130 bushels *per* English acre), and on heavy land he has gone the length of 70 bolls. The day the lime comes to the field, a man follows the carts, and covers it up immediately with earth, by which, generally in a few days, it is reduced to powder. When in that state, it is spread on the land. After trying several other methods, this was found to be the best. The improvement effected by lime on that property has been very great.

4. The slacking of lime completely is a most important operation. The common mode is, to lay it in heaps from the kiln upon the ground intended to be limed; but this, although the most expeditious, is by no means the most advantageous method. In the first place, if the lime is not all of the same quality, (which is seldom the case,) the best lime commonly dissolves first, and the inferior quality continues unslacked; so that it must either be spread in that state, or the good lime must be allowed to receive too much moisture, or again to re-absorb its fixed air, both of which should be prevented. The best mode of slacking, is to lay down the shells in a heap near to water, and by

* Communication from Mr. Walker of Mellendean.

once turning and watering the whole mass, it is reduced to a complete powder; in which state it should be applied to the soil, and ploughed in immediately with a shallow furrow, when there is no doubt but it will mix more intimately with the soil, than by the former method.* This plan, however, is attended with an additional expense of considerable magnitude.

The necessity of slacking calcined lime, as soon after it is burnt as possible, is obvious. If any sudden rain should fall, it would be converted into mortar; no art can then separate it, and mix it equally with the soil; nor would double the quantity have the same good effect. Even after it has been reduced to powder, if any rain should happen to fall, or if by any means it receive too much moisture, while it lies thin spread on the surface of the field, it will partly be formed into hard insoluble cakes, and may remain in that state for years, without mixing with or being of the least benefit to the soil. In the course of repeated ploughings, Mr. Patterson of Castle-Huntly has observed pieces of hard lime come up, as insoluble as if they had been pieces of an old building.

Considering these circumstances, I was much pleased to find, that a mode had been discovered by Mr. Niel Ballingal in Fife, which obviates these difficulties. His plan is, to lay the calcined lime down on any thick head-ridge of good earth, within the field where it is to be applied, and the instant it is so, two men are ready to make up a compost of the lime-shells and earth; three cart-loads of earth to one cart of shells, raised to a ridge long and narrow, five feet high, that rain may not enter it. The moisture in the earth slacks or reduces the lime to a powder; it swells to a considerable bulk, and then all cracks and openings are closed with a spade, and a little more earth put over the whole. In this way, he has had it frequently mixed up for six months, and in one particular instance fifteen months, before it was carted away; and yet when carried on to the land and spread, the whole mass put on the appearance of white lime, flying with the wind, as if newly from the kiln. This mode he means always to follow, being certain of its advantage. It can be mixed as intimately with the soil as if new from the kiln, and he has had crops from it, in this way, superior to an equal quantity of hot lime† both tried without dung. The application commonly is to the summer-fallow: he has also applied it to pasture, quite hot, and in compost as above described, and found both answer well: but the time of application was July, and he soon found, that it ought to lie at least one year or more before the field was ploughed.

Mr. Ballingal having used from 500 to 1000 bolls *per annum*, for several years, his experience may be confidently relied on. He remarks, that lime, if exposed to rain, or even to frost, and slacked like mortar, loses half its effect; no care can then mix it intimately with the soil. His land is wet, and often when the lime is driven unfit for carting upon the field, nor are the ridges prepared for spreading the lime; without having fallen upon such a plan, therefore, he could never have used lime to equal advantage. He adds, that an intelligent neighbor of his, brings his lime from the kiln, lays it in small heaps, about a firlot of shells in each heap, or four heaps *per* boll, on the fallow; covers these instantly with earth, which slacks the lime, and when it is completely so, he spreads it in powder, quite hot, on the fallows, and ploughs it in with a light furrow. This saves labor and expense. He never uses water in slacking lime, and the effects of his practice are very good; the earth, or rather the moisture in it, slacks the lime most completely, and no water is necessary.* This is an excellent practice, and very common in many counties: and many intelligent farmers prefer it to the other plan, which they think would be attended with too much expense to be generally imitated. At the same time, an intimate mixture with the soil is of the utmost importance in the application of lime; any plan that contributes to that object merits attention.

4. Mr. Dudgeon, of Primrose-Hill, considers it to be the most advantageous mode of applying lime, to lay it on in a powdery state, upon ground when under summer-fallow, before the fallow receives the last furrow, and then to mix it intimately with the soil, by harrowing before it is ploughed in. In regard to liming fallows, Mr. Rennie of Phantassie observes, that it is the most profitable mode of application, if it is laid on at a proper season. He has been in the practice, for these ten years past, of laying lime on his fallows, from the 1st of April to the 1st of October, and always found, that the first laid on produced the best crops, which he ascribes to its being more minutely mixed with the soil, by the more numerous ploughings and harrowings, and of course the fermentation more complete, than what is laid on late in the season: June and July, therefore, are to be preferred, so that the lime may be completely mixed with the soil before the crop is sown; and as it is both a valuable and expensive manure, too much attention cannot be given it.

Applying lime to green crops is attended with more difficulty. From observation and practice, Mr. Rennie recommends that, for a crop of turnips, lime should be laid on so early in the spring as to admit of two, if not three ploughings, and as many harrowings, after it is laid on, so as both to mix it properly with the soil, and also to let it have time to cool in the land, otherwise it will be very apt to cause the loss of the turnip crop.

Mr. Park of Windy-Mains is accustomed to lay lime on the land intended for turnips, immedi-

* Communication from Mr. Rennie of Kinblethmont.

† This is an important fact, it being generally supposed that when inserted in the form of hot lime, in a state of perfect powder, its effects are greater and more immediate than in any other way. By Mr. Ballingal's plan, the lime can be carried to the field in autumn, or even in winter, which, though an old practice, could not be done with equal safety, as under the proposed system.

* A correspondent contends that lime is best laid on the land in small heaps, and immediately covered with earth, which in a damp or moist season slacks or falls it; but he frequently puts on water from a water-cart, which slacks it directly, and it is immediately spread in that quick state, harrowed, and ploughed in, when it mixes most intimately with the soil. Lime should be in powder, and the land in a powder-like state, when it is laid on.

ately after harvest, when the land has got the first furrow. He first makes a pair of harrows go backward and forward on each ridge to smooth it, then lays down the shells in huts about 60 or 80 bolls *per* acre Scotch; as soon as it is powdered, he spreads the huts, and harrows the field, and lets it remain till May, when it may be prepared for receiving the dung.

Mr. Brodie of Garvald, who has long paid peculiar and successful attention to the management of lime, adopts the following plan in applying lime to his turnip land. After the ground intended for turnips has got a winter and a spring furrow, the lime is laid on, and well harrowed in: it then gets another furrow before making up the drills, and is again well harrowed, for the double purpose of getting the lime intimately mixed with the soil, and taking out any quickens, or other weeds, by which the field is infested. The turnips are sown in drills, both as being better for the turnip crop than when sown broadcast, and the lands are got better cleaned, either from annual or perennial weeds. It is reckoned an advantage, to have the lime got forward during the former summer, previous to its being laid on for turnips; for on a turnip farm, there is so much spring labor, that it is hardly possible to drive any considerable quantity of lime, from any distance, at that season of the year. When it is new from the kiln, it is so hot, that it is apt to dry up the moisture necessary for bringing the turnips into leaf; in this case, the lime ought to be laid on a piece of very dry ground, in large heaps, and thrown up to a considerable thickness, which will make it in a fine state for laying on in the spring, that is, neither in a wet, or in a very hot state.

In regard to green crops, Mr. Paterson of Castle-Huntly thinks it better to lay on the lime after the green crop, rather than before it, so as it may be well mixed with the soil, before it comes in contact with potatoes or other roots, it being apt to burn and blister their skins, and to spoil their appearance, if it does no more mischief. Some farmers, however, have put lime upon the ground after it is planted with potatoes, and harrowed it in. But this practice cannot be recommended.

The application of lime to grass, particularly on light or dry soils, and where the land has been long pastured, is a most advantageous system, if it is soon after to be brought into culture; otherwise, being exposed to the atmosphere, with but little admixture with the soil, it cakes and hardens, and in some measure re-assumes that unproductive quality, which it possessed, previously to its being reduced to a caustic state. It may be applied after the land has been a summer in pasture, or cut for hay; but the ground should be made as bare as possible, otherwise it will be difficult to spread it equally over the sward or surface. The lime should be laid on in autumn, and the land should remain in grass for another season, till it is absorbed. If intended to be applied to old ley, either lay the lime on one year before cropping, letting it lie upon the surface, or lay it on about Martinmas, and let it lie on the surface till February, then plough it down, and sow the ground when the weather is suitable. Suffering the ground to remain for some years in grass, is certainly the best preparation for lime, as it has then fresh mould, and vegetable matter, to act upon.

Mr. Cuthbertson recommends, that no lime should be laid on high ridges that are intended to be flattened; the ridge should be brought to the same round in which it is intended to remain, before that operation is accomplished, because, in performing it, there is a great risk of burying the lime. Mr. Barclay remarks, that when the application is made, the land should not be too wet; and it is necessary, at all times, to have the lime brought to such order, as neither to fly off with the wind, nor go into clods in the spreading.

Mr. Brodie of Garvald observes, that some speculative agriculturists recommend liming upon the surface, to extirpate the heath, and improve the pasturage, without attempting to bring ground under the plough, as the soil and climate may be unfit for the raising of grain. If the lime is at any considerable distance, there is reason to suspect that this would not turn out a profitable concern. At the distance of eight or ten miles, a good liming would not cost less than £10 or £12 the Scotch acre. It cannot be expected that this improvement, on such hills as those of Lammermuir, would even pay the interest of the money. Gentlemen proprietors may improve at this rate, but a tenant would be extremely imprudent, were he to throw away his capital, without a prospect of being repaid. It is surely better to lime land worth the improving, to bring it under the plough, and then to take a few corn crops to refund the expense. The tenant is thus reimbursed, and has an ameliorated pasture, as the reward of his industry and superior management.

Though liming the surface, "to extirpate heath, and improve pasturage," may not be a profitable concern on old swards, it is proper to observe, that when land is broken up, merely for the sake of improving the pasturage, the best, and most economical mode is, to apply lime *to the surface*, and to harrow it along with the grass seeds. A great extent of hilly pasture has thus been improved by Mr. Dawson, and others, in Roxburghshire.*

6. Mr. Kerr, the intelligent reporter of the husbandry of Berwickshire, has transmitted to me the following calculation of the expense of liming. The lime he used was brought by sea to Eyemouth; and the price, besides carriage, amounted to 2*5d. per* boll, in shells, each boll containing four Winchester bushels; hence to lime an acre of land with 35 bolls, will cost about £3, 15*s.*, besides carriage and spreading, which, the distance being short, may amount to 10*s.* more, or £3, 5*s. per* acre; and as this operation was usually repeated twice during a lease of nineteen years, liming, in his situation, may be considered as a yearly charge of 10*s. per* acre.

How astonished would not many farmers be in other counties, when they hear that Scotch farmers subject themselves to an expense of 10*s. per* acre *per annum*, for lime alone, a sum not much inferior to the average rent of land in many English counties. But the expense is well bestowed, were it only from the benefit thence to be derived in the cultivation of green crops of every description. For though such crops can be raised by large quantities of dung, yet where calcareous

* For a detailed account of this excellent method, as practised by Mr. Dawson, see the Farmers' Magazine for March, 1812.

substances are applied, as Mr. Brodie of Garvald has found by long experience, a less quantity of animal manure will answer the purpose. This is making the farm-yard dung go farther, with more powerful and more permanent effects; and from weighter crops being thus raised, the quantity of manure on a farm will be most materially augmented.

7. The use of pounded limestone, where fuel is scarce or dear, was strongly recommended by Lord Kames. He observes, that three pounds of raw lime is, by burning, reduced to two pounds of shell lime, though nothing is expelled by the fire but the air that was in the limestone, the calcareous earth remaining entire. Two pounds of shell lime, therefore, contain as much calcareous earth as three pounds of raw limestone. Shell lime of the best quality, when slacked with water, will measure out thrice the quantity; but as limestone loses none of its bulk by being burnt into shells, it follows, that three bushels of raw limestone, contain as much calcareous earth, as six bushels of powdered lime; and, consequently, if powdered lime possess not some virtue above raw limestone, three bushels of the latter, *beat small*, should equal, as a manure, six bushels of the former. These suggestions, however, have not been acted upon, probably owing to the difficulty and expense of beating the limestone sufficiently small. At the same time, the advantage derived from the use of limestone gravel in Ireland is, however, highly favorable to Lord Kames' doctrine.*

8. It is an ascertained fact, that lime is of no advantage in the neighborhood of Edinburgh, where the land has been long accustomed to aration and city manure. Mr. Allan of Craigrook, near Edinburgh, has given lime the fairest trial by liming one ridge, the whole field over, at the rate of 60 bolls *per* acre, and leaving the other unlimed, and he has uniformly found, that the liming has had no effect. The reason, probably, is this, that the land having been so often manured with Edinburgh street-dung, which frequently contains a proportion of shells, the use of stone lime is thereby superseded. Indeed, some are of opinion, that the land in the immediate vicinity of Edinburgh had been abundantly limed at some former period, which, in addition to the calcareous matter mixed with the street-dung, renders any additional liming unavailing.

Mr. Hume of East Barns finds, that lime does not answer on his farm near Dunbar, which he attributes to the great quantities of sea-ware, mixed with shells, which have been laid on these lands from time immemorial, and their having been formerly under constant crops of corn, and never in grass till lately, and even now only one year at a time. It is well known, he adds, that lime acts best on land that has been much in grass. Any local circumstances of that sort, however, cannot diminish the credit of a manure, of such essential importance to the improvement of the country.†

* It would be extremely desirable to ascertain whether limestone gravel might not be found in Scotland; to the discovery of which, I hope the attention of that public-spirited institution, the Highland Society of Scotland, will soon be directed.

† It is an interesting object of inquiry, whether lime is equally efficacious on the sea-shore, as in the inland districts? It is well known that gypsum is not.

GENERAL VIEW OF THE IMPROVED HUSBANDRY OF SCOTLAND.

From Sinclair's Husbandry.

In a communication from my respectable friend, Sir Joseph Banks, he stated, that "agriculture has derived, is deriving, and will derive, more benefit from Scotch industry and skill, than has been accumulated, since the days when Adam first wielded the spade."

I hope that the following general view of the improved system of husbandry, as established in Scotland, will justify that observation.

The foundation of improved agriculture is certainly laid, in the best cultivated districts of Scotland, in as great perfection as it possibly can be in any country. The farms are usually of a proper size;—the farmers, in general, have capitals adequate to their cultivation; they are bound to pay the landlord such a proportion of the value of the produce, as renders it necessary for them to be industrious and economical, and to acquire all the skill, in the art of husbandry, to which they can have access;—their leases are commonly of such a duration, as to encourage judicious expenditure in the improvement of their lands, with the prospect of an adequate return;—the covenants contained in their leases are sufficiently fair, being almost, in every case, well calculated to promote, and not to retard improvement; a liberal system of connexion is established between the landlord and the tenant;—and the characters of those, by whom the labors of agriculture are carried on, whether farmers, apprentices, farm-servants, or common laborers, cannot be surpassed by those of the same description of life in any other nation. The experience of Scotland has likewise proved the superior advantages of having married servants on large farms; by means of which, the population of a country is increased, and the kingdom filled with sober, healthy, and industrious subjects.*

The various points which require to be attended to, previous to the actual cultivation of an arable farm, are in general ascertained, by the practice of Scotland, with a degree of precision hitherto unexampled.

The farmers of that country have established it as a principle, that the position of a farm-house and offices ought to make a material difference in the rent of a farm;—they have ascertained the best construction of farm-houses and offices, uniting economy and convenience;—they have pointed out the best size and shape of fields, by means of which, much land is rendered productive, that would otherwise be wasted in useless fences, and much labor in their cultivation saved, insomuch that where the fields are large, five ploughs will do as much work as six can in small fields, and every other part of the cultivation of a farm will be executed with less power, in nearly the same proportion;—they have likewise pointed out the inconveniences attending expensive fences, which are more ornamental than useful to a country;—they are fully aware of the importance of draining, and have practised it with success;—they have

Sea-ware contains kelp, which, from the alkali it possesses, may act as a substitute for lime.

* These particulars are explained in the three dissertations of Part 2.

ascertained, that by the introduction of good roads, the value of a country will be greatly increased;—their instruments of husbandry are cheap, and well constructed; their ploughs excellent, worked by two horses,* and peculiarly well calculated for general use; and their carts superior to any other for agricultural purposes;—their live stock are valuable, well calculated for their soil and climate; and their horses, not only well adapted for the labors of husbandry, but maintained in such a manner, as to render them capable of performing a great deal of labor;—in some cases they have tried a partial use of oxen with success, more especially in thrashing-mills;—nor do they neglect to pay a proper degree of attention to the articles that ought to be raised upon a farm, according to its soil, its climate, its elevation and exposure, and its situation in respect of markets.

In regard to the actual cultivation of an arable farm, many points of infinite importance have been ascertained by the experience of Scotch farmers, in a manner the most satisfactory. They have ascertained the proper length, breadth, and shape of ridges;—in the use of putrescent, and still more of calcareous manures, they have made great improvements; they have proved, beyond the possibility of doubt, the advantages of deep ploughing;—they have completely ascertained the advantages of summer-fallowing, where soils are either of a clayey nature, or are incumbent on wet subsoils;—they have carried on with success, some essential improvements in the cultivation of various crops, in particular in regard to those important articles, turnips and potatoes;—they have also brought to a high degree of perfection the course of crops calculated for different soils; and have ascertained the rotations for which each description of soil is respectively best adapted;—they cultivate in drills, beans, turnips, and potatoes, in a manner not to be surpassed for its excellence, and they have laid it down as a maxim, that crops of grain should be drilled, where the land is sown in spring, particularly where it is subjected to annual weeds;†—they have also made some improvements in harvesting grain; in particular, the plans of cast-iron pillars and bosses, are admirable inventions for a wet climate, by means of which, the harvesting of grain, and of pulse in particular, may be completed in half the usual time;—they have brought the cleaning and thrashing of grain to the highest degree of perfection; almost every individual, who has any claim to the character of a farmer, having fanners in his possession, and thrashing-mills having become almost equally general;—they have carried, to a great extent, the practice of soiling horses, and even cattle; and have proved, by decisive experiments, the superiority of that plan;—they have restricted the practice of preserving permanent pastures within reasonable bounds, and have proved, that the convertible system of husbandry, may be generally adopted, to the great benefit of the landed proprietor, and of the public.

These are circumstances connected with the improved system of husbandry established in Scotland, the existence of which, I trust, is abundantly proved in the course of the preceding observations.

The result of this system is in the highest degree satisfactory. In all the corn districts, where the convertible husbandry is thoroughly established, greater crops are raised, and higher rents are paid,* than in any other part of the British dominions, and, what is equally remarkable, the condition or circumstances of those engaged in agriculture evidently bear the like marks of abundance. Without enlarging upon these matters in this place, I may only add, that the produce of crops, in good seasons, and in fertile districts, is calculated to be from 32 to 45 bushels of wheat, from 48 to 55 bushels of barley, from 60 to 75 bushels of oats, and from 30 to 35 bushels of beans, Winchester measure, *per* statute acre. As to green crops, 30 tons of turnips, 3 tons of clover, and 8 tons of potatoes, *per* statute acre, are no uncommon crops. Any system that can produce crops of so superior a description, even on fertile soils, is well entitled to imitation, more especially when it is accompanied with great economy in the expense of cultivation.

Forty-four years have now elapsed, since one of the ablest writers on agriculture in modern times, (Lord Kames,) pointed out the imperfection of Scotch husbandry; and it is singular that, with hardly any exception, these imperfections have since been removed. Had it not come from such high authority, it is hardly possible to credit, that within the memory of so many persons now living, our agriculture could have been so miserably deficient as it seems to have been at that time. The learned Judge represents our instruments of husbandry as sadly imperfect;—our draft-horses as miserable creatures, without strength or mettle;—our oxen scarcely able to support their own weight, and ten going in a plough, led on by two horses;—the execrable husbandry of infield and outfield generally established;—the ridges high and broad, in fact enormous masses of accumulated earth, that would not admit of cross-ploughing, or of proper cultivation;—shallow ploughing universal;—ribbing, by which half the land was left untilled, a general practice;—summer fallow, though common in three or four counties, yet only creeping on in others;—over the greater part of Scotland, a continual struggle for superiority between corn and weeds:—the roller almost unknown;—no harrowing before sowing, and the seed thrown into rough uneven ground, where the half of it was buried;—imperfect rotations of crops;—little skill in harvesting;—no branch of husbandry less understood than manure;—potatoes in general propagated in lazy-

* In Norfolk they use only two horses in a plough, but four horses are commonly allowed for each plough, two for a journey of five hours in the morning, and two more for another journey of five hours in the evening.

† It must be admitted, at the same time, that the drilling grain crops, is more generally practised in England, than in Scotland, but that is not the case in regard to beans, turnips, and potatoes.

* Mr. Curwen, in his Report to the Workington Society for the year 1810, p. 86, states the rent of fertile land in East Lothian to be, £6 *per* Scotch acre, and the produce, 40 bushels of wheat, 60 of barley, 90 of oats, excellent beans, weighty crops of turnips, and most luxuriant crops of clover. It is proper, however, to observe, that this is only applicable to the more fertile soils. A farm of 330 acres of arable land near Dunbar has lately been let at £8, 2s. *per* Scotch, or £6, 10s. *per* English acre.

beds;—swine but little attended to;—and very few farms in Scotland justly proportioned to the skill and ability of the tenant.* What a contrast to the description I have just given, of the husbandry of Scotland at the present period!

Among the circumstances which have occasioned so extraordinary, and so rapid a change, in the husbandry of Scotland, that turn for reading, by which the Scotch farmers are so peculiarly distinguished, though already pointed out, ought to be more fully dwelt on. Nothing can be more absurd than to imagine, that the communication of information by printing, which has promoted the advancement of every other art, should be of no use in agriculture. It is not recommended, that a practical farmer, should take for gospel what he reads in print, and should alter his whole system accordingly; but let him reflect on what he reads, let him try, on a small scale, useful experiments, and let him extend them when they are found to answer. At any rate, he may find in books a number of useful hints, which may be entitled to further inquiry. Hence the writings of Kames, and those of Anderson, Dickson, Home, Wight, &c. in Scotland, and those of Arthur Young, Marshall, and others, in England, gave a great spur to the improvement of Scottish husbandry, by directing the attention of the farmer to the principles of that art to which their lives were devoted.

The practice adopted by the Scotch farmers, of travelling to England, and in some cases even to foreign countries, removed a cloud of prejudices, which could only be speedily, and completely eradicated by ocular inspection.

No circumstance, however, had a more powerful influence in promoting a spirit of improvement in the northern part of the kingdom, than the formation of a Board of Agriculture; and from that era, in the opinion of the best informed agriculturists in Scotland, may be dated that wonderful change which has taken place in Scottish husbandry. In consequence of that establishment, as remarked by an intelligent farmer,* "a general desire seized all ranks to promote internal improvement. By means of that institution, great numbers of new men were brought forward to public notice, whose names otherwise would probably never have been heard of; and these being chiefly practical people, in other words, persons professionally concerned in farm management, agriculture, by their endeavors, was rescued from the hands of theorists, and a revolution of no small extent accomplished in rural affairs. Before the Board was instituted, the bond of connexion amongst agriculturists was slender, and served few useful purposes, each standing on his own strength and information, and unless in the case of those who travelled about to collect useful information, (and the number of those, at that time, was not great,) they new little more about the practices of conterminous districts, than those of China, or the most distant countries. The establishment of the Board did away at once all those evils and difficulties: a common fortress, erected for the benefit of all agriculturists, and to which each might resort for advice and protection, was immediately recognized. It made farmers, who resided in the most distant quarters of the kingdom, acquainted with one another, and caused a rapid dissemination of knowledge amongst the whole profession. It did more—the art of agriculture was brought into fashion; and this being the case, old practices were amended, new ones introduced, and a degree of exertion manifested, which had never before been exemplified in this island. The numerous surveys of husbandry, executed under the authority of the Board, were of singular advantage also, because they brought to light the practices of every country; and whilst they pointed out the obstacles which lay in the way of improvement, stated the most effectual methods of removing them. The very collision of argument, which such discussion occasioned, was of advantage, causing agriculturists to investigate the principles of the art which they professed, and inducing them to search after new channels of improvement. In a word, the Board, in a few years, collected a mass of agricultural information, hardly to be equalled, and not to be exceeded, by the accumulated stores of every other nation."

Mr. John Shirreff likewise attributes the rapid improvement of Scotland, to the interesting information communicated by the Board of Agriculture, at a time when the minds of men were qualified, from education and observation, to put a proper value on it, and whilst their capitals, arising from that powerful stimulus to improvement, leases, enabled them to execute those improvements which this interesting and various information suggested.

In a communication from Mr. Charles Alexander, a respectable farmer near Peebles, it is observed, that the publications of that Board, and other recent works on farming, in particular "The Farmer's Magazine," printed for the express purpose of promoting the views of the Board, were read with avidity; that a spirit of inquiry was thus excited, and that improved agriculture was universally considered to be *a sort of coining of money*. Hence a large share of capital, that did not originally belong to agriculture, and never was acquired by it, was thrown into the scale; an unprecedented competition arose for purchasing and leasing land; an increased spirit of agricultural improvement was the result, the effects of which soon became almost universally conspicuous.

The exertions of many other public-spirited institutions, in particular those of the Highland Society of Scotland, were of the greatest service; and a number of provincial societies, in their several districts, propagated the spirit with success.*

But information and skill would have been accumulated in vain, had it not been that, by the extension of paper currency, and the establishment of banks and branches in almost every county in Scotland, the farmers were furnished with credit, and supplied with the readiest means, of converting the produce of their farms into the circulating medium of the country, and were

* See Kames's Gentleman Farmer, Appendix, Art. I, On the Imperfection of Scotch Husbandry.

† See Brown of Markle's Treatise on Rural Affairs, vol. 1, p. 20.

* The advantages of provincial societies are ably explained, by Sir George S. Mackenzie, in the Rossshire Report, p. 332.

thence enabled, not only to continue their exertions, but to lay out considerable additional sums on the improvement of their several occupations.

These circumstances combined, in addition to those already pointed out, will, I trust, account, in a satisfactory manner, for the great advancement that has been made in Scottish husbandry.

THE FARM AND FARMING OF THE REV. J. H. TURNER.—NO. IV.

For the Farmers' Register.

In my last, No. 3, I promised to take up the hacknied subject of rotation. But my pony (Monsieur Tonson again) stands at the door already caparisoned, and by her wistful looks, invites me to another excursion. I now have a strong bit on the frolicsome jade, and I intend to hold a tight rein, so that I think there is but little danger of her again running away with me.

I wish to say a little more about that harassing thing called *debt*. "A burnt child dreads the fire;" and I have been so hampered and harassed, and have suffered so much on this score, that I would warn all farmers against it, as one of the sorest and most inconvenient troubles that can come upon them. If any are already involved in this dreadful vortex, all I can say is, that they must get out—*as they can*. Nothing is easier than to avoid debt, when fairly out of it. Here, as in many other cases, one ounce of *prevention* is worth whole pounds of *cure*. It is simply to make the matter turn on these two questions: Do I really *need* the thing desired? And am I in circumstances to pay for it? If these two questions can be answered in the affirmative, then it is safe to buy. On any other principle it is always unsafe, and therefore all idea of purchase ought to be banished from the mind.

But it is really a little singular how very insidious this thing often is. The article wanted is a *little* one, and its cost a *mere trifle;* or the circumstances are so peculiar, as to constitute an emergency. The old carriage has become quite shabby, and wife insists upon it that a new one is indispensable; or Miss appeared at church with a new frock made up in the new fashion, and this attracted more attention from all the *young* people than the sermon did; and for this very *solid* reason, all the misses, whether their fathers can pay for them or not, must have a new fashionable dress also. It is also astonishing how important a bearing that word *decency* is made to have upon expenses of this sort. I *once* had a very exalted opinion of that word. I still think it a very comely one. But when I see that it is made the occasion of throwing aside the old carriage, or the old coat, though still comfortable, and of going in debt for new ones, I candidly confess that my attachment for the word is considerably weakened. The practice, with all its *decency*, is, to say the least, a very inconvenient one.

The propensity to buy things, not because they are *needed*, but because they are *cheap*, cannot be too strongly reprehended. The *men* are commonly keen enough at making a bargain; but the fair sex will excuse me when I say that, in this respect, they certainly take the palm from us. If a *good* bargain is offered, they cannot resist the temptation of making it their own. Good, prudent souls, like the industrious ant, they must be storing away for future wants. Some time ago, the following characteristic incident took place when I happened to be present. Madam had just returned from town, whither she had gone to purchase some necessaries for the family. After producing these, in which she seemed to take no particular interest, she proceeded to display, with great delight, the rich stores of *bargains* she had made. "See," said she to her good man, "here is a new shawl for Julia, and a new bonnet for Emily, and a new frock for little Sarah, all in the newest fashion. Now don't you think them very beautiful?" "Yes, my dear, I think they are; but," continued the good man, "I thought our daughters were already supplied." "They are," replied the lady; "but these were *so very cheap*. Why what do you think I gave for the whole?" "I can't tell, my dear," was the loving reply; "but one thing I know—that if you continue to buy things at this rate, because they are *cheap*, I shall soon be unable to procure *necessaries* for my family."

Our merchants, too, are often to blame in this matter. A customer enters the store. Both partners of the concern and all the clerks directly put on all the airs of their politeness. "Will you allow me to wait on you, madam? What will you have, madam?" And, without waiting for a reply, the shelves are immediately stripped of their contents, and the counter loaded with goods. "Pray, sir, don't give yourself so much trouble." "No trouble, madam; it gives me great *pleasure* to wait on you. See this beautiful goods—and cheap! I never had such cheap goods before. I bought it the other day at auction; and I can sell you the greatest bargain in town." Thus the voluble merchant runs on praising his goods, as the prettiest, the best, and the cheapest, until madam is induced to buy, perhaps beyond her ability to pay. The merchant will accommodate her as to credit also, and then raise a great clamor, that the *country people* will not pay their debts.

These were my cogitations during my excursion, and I hope the reader, ladies and all, will excuse me for presenting them just as they occurred. I now retire to the writing desk, and rotation in crops is the next topic that I am to treat of.

This, at various times, and in various forms, has been the fruitful source of discussion among our best and most influential farmers. Perhaps there is no subject, in the whole routine of farm management, on which more thought and ink has been expended. And even now, the contending parties seem as far from entire agreement as they were several years ago. Almost every farmer, especially those who go into the business on a large scale, seems to think that some rotation is necessary; but it is a rare thing to meet with two whose theory and practice precisely agree in this matter. The old rotation used to be corn and wheat, and then corn and wheat again. But finding that on this plan there was a constant falling off in the crop, until the land would produce neither the one nor the other, a *third* year was added, in which the land was allowed to rest. The rotation then was, corn, wheat, rest. To this was afterwards added a *fourth* year; and then the case stood thus: the first year a little corn, the second still less wheat, the third rest, as far as the

ravages of the famished cattle would let it have rest, and the fourth year a crop of briers, sassafras, persimmon, &c. So things continued, our agricultural prospects becoming more and more gloomy; our population starved out at home, and forced to the west in quest of land on which they could live, until some one conceived the idea of interspersing a grass crop, which has proved itself to be the great renovator of worn out lands. The rotations are now a vast deal more judicious than formerly. Indeed, I know of no rotation now, in which grass is not made to hold a conspicuous rank, and to this some have added peas and oats, to be turned in, in a green state. But still this subject continues to be a very vexed one, no general agreement having as yet been fixed on, as to how these several crops ought to succeed one another.

Hitherto I have maintained an entire silence on this question; and it has been a source of considerable amusement to me to watch the progress of that good natured and genteel controversy, in which some of our most worthy and substantial farmers are still engaged. And I think it more than probable that it would be good policy in me still to maintain the same attitude. But as I shall make an attack upon no person, nor upon the favorite system of any one, but simply express my own sentiments, I hope my fellow farmers will take them for what they are worth; and I hereby bespeak their kindness, that if they think proper to inflict upon me a castigation, it may be as moderate and gentle as possible.

And now, that I may enter on the subject at once, I would inquire, what is the great object of all farming, rotation among the rest? It is (if I mistake not) to derive as large a product as possible from our lands, and at the same time to leave them in a condition to produce as large or even a greater amount in the succeeding crop. If the crop remain uniform and stationary, there is evidence that the fertility of the land is the same; but if there be an increase or falling off of the crops, there is evidence of the increasing or decreasing fertility of the land. The power of production is therefore the great criterion by which we are to test the true condition of our lands.

Now the great desideratum in farming is to make the lands highly productive, and at the same time maintain them in a state of continual improvement. He who has arrived at this point, has reached, as I think, the "Ultima Thule" of good and skilful management. But the great matter is, by what rotation, or other expedient, is this to be effected? To this I reply, that this whole vexed question, on which there is almost as great a variety of opinions as there are different farmers to entertain them, is with me reduced to the limits of a mere "nut-shell." My theory is, that all crops whatever, whether corn, wheat, clover, or what not, especially if permitted to mature themselves, and then removed from the land, are, from their very nature, *exhausting*. This being conceded, the matter is made very plain. If the land undergoing cultivation is already rich, and we merely wish to maintain it in its present condition, all we have to do is to return to it an amount equivalent to that removed. Or if the object be to increase fertility, then the plan is to give it *more* than is taken away. And in adjusting this account, the land, if I may be allowed the expression, is rigidly and scrupulously exact. It will tolerate no cheating nor imposition whatever. If more be taken than a just proportion, the barn or corn crib will be filled, but it will be with a corresponding injury to the land. Whereas, if we proceed on a liberal principle, the land will not be outdone in generosity, but will open her kind bosom and pour forth a bountiful supply. It is, therefore, in vain, as I think, to talk of one crop as an enricher, and of another as an exhauster. They are *all*, grain, grass and every thing, exhausters; and they are exhausters in proportion to their own amount. If the crop be a heavy one, the exhaustion is heavy, but if it be a light one, the exhaustion is proportionably light. Now I do not wish it to be understood, that I consider all crops *equally* exhausting. Some for instance have broad leaves, for the express purpose, as I suppose, of deriving a large portion of their sustenance from the atmosphere. Now just in proportion as support is derived from this source, a less amount is needed from the land, and therefore less injury is done to the land in producing its crop. But the sentiment I wish to inculcate is, simply, that the injury done by one crop can never, by any rotation whatever, be repaired by another. On the other hand, this second crop, when removed, does but increase the injury done by the first.

But it will be inquired, do you advise a succession of the same crop on the same land, without regard to variation of any kind? To this I reply, that I see no objection to it, *provided* there is fertility enough in the land to sustain it; or in default of this, that the deficiency be supplied from some foreign source. The general theory on this subject, if I understand it, is the following: that the land contains certain ingredients; that some of these ingredients are suited to one crop, whilst others are adapted to other crops; and that these several crops, during their growth, appropriate to themselves only what is proper for them, leaving the residue to others which are to follow. Now, if this theory be true, then it follows that rotation is not only *necessary*, but that cropping cannot be carried on without it. This whole theory turns upon this one point: Are there in fact peculiar ingredients in the soil, suited to a particular crop; and may these be so taken up by that crop, as to render the soil unfit to reproduce the same? To this I reply, that there is one ingredient which, when exhausted, is destructive not only to *that* crop, but to all other crops, and that ingredient is *fertility;* and my theory is that this ingredient is just as necessary to one crop as another. I will, therefore, with the risk of a severe castigation from some brother farmers, frankly acknowledge, that I have no great faith in any rotation, from which regular supplies of manure of some kind are excluded. I will even go further, and say that, in my view, it makes but little difference what the succession of crops may be, provided there be a constant supply of enriching materials equal in amount to the crop which is removed.

And now, as I confidently expect to be attacked for this very heterodox sentiment, I will take the liberty of making my defence in advance. And here I would remark, that what I call fertility, a term understood by every body, is expressed by different writers by different names. Professor

Webster (I think it is) calls it *humus*, and Professor Dana calls it *geine*, and Liebig calls it *ammonia*. Now, without resorting to long quotations, which would merely cumber this piece and add nothing to the argument, I will simply state that these three learned gentlemen do agree that the above are the only ingredient necessary to the thrift of a plant; and that where they exist in proper proportions in any soil, that soil is a fertile one. Dr. Dana expressly says, (Second Report of the Agriculture of Massachusetts, page 165,) "if we can induce the state of geine best fitted for each plant, then adieu to the doctrine of the necessity of a rotation of crops." But in a plain discussion, such as this is intended to be, I would rather rely upon common sense, supported by observation, than upon any authority of the learned whatever. What are the *facts* then in the case? The Rev. Mr. Colman, commissioner of the above report, states it as a fact, that he saw a rich alluvion field on the Connecticut river, the proprietor of which told him that, without any manure, it had continued to produce good crops of wheat for *thirty* years in succession. In corroboration of this, I well recollect that, when I was a boy, my mother had her cotton patch, which continued to produce the same crop year after year, for I know not how long a time. There was also on the same farm a sweet potato patch which shared precisely the same fate. In addition to this, it is within my knowledge, and can be proved by hundreds of others, that the late Dr. Tazewell continued to cultivate corn on one of his lots near my farm, for more than ten years in succession; and that his last crop was inferior to his first, only in consequence of the exhaustion of the land. Here then is wheat, and cotton, and sweet potatoes, and corn, not one of which is dependent on a *rotation* of crop for their success.

But there is another department, in which cropping is going on, on a much larger scale, in which, as I think, I am borne out in the above position. This great department is the world, and the crops are the immense forests with which it is covered. Now here is a great crop produced, and according to my position, it must be at the expense of an immense exhaustion. Here too is no relief arising from rotation, for the same crop has been on the land for thousands of years. And yet this same good farmer, Nature, has so contrived, that without the least rotation in all that time, the fertility of all that land of which she has had the exclusive management, has not only been maintained, but has constantly improved. Nature's farm presents at this time a most singular anomaly of bearing an increasingly heavy crop for thousands of years in succession, and is at this day in better heart, than it was when she took it in hand. It is simply because nature's wants are all *real*, and therefore *few*. Her main object has been, what ought to be the main object of every farmer, to keep up the fertility of her land. And how has she accomplished it? Not by a rotation, but simply by returning the crop to the land which produced it.

But whilst nature has constantly set this wise and laudable example, man has come in, and though endowed with intellect, and calling himself the "lord of creation," has made a very poor affair of *his* farming. He has taken his little patches, and under the growings of his artificial wants, has taxed them to the full amount of their ability, and appropriating the whole products to himself, and giving back nothing to the lands, has reduced both them and himself to a state of beggarly starvation. And now he is trying to repair the injury, by a rotation of crops. This, as I think, is only calculated to make matters worse. When I see land refuse to bring one crop, I consider this as plain evidence that it will refuse to bring another. The rotationist however is of a different opinion. He tries corn, and fails, he then tries wheat, and fails also, his next effort is with clover. here is another failure, his last resort is to black-eyed peas, these may be *sprouted*, but there will be a failure in this crop also.

Now what can be the cause of all these successive failures? Some *special* ingredient is wanting is the soil. Yes! this is the truth. And what is it? Learned men call it humus, or geine, or ammonia; but I call it by the vulgar name of *manure*. Put manure on the land, and it will bring corn, and wheat, and clover, and peas, and any thing else, and that without regard to any particular rotation. The very best rotation, then, (and gentlemen will surely thank me for solving this difficult problem for them,) is that which brings the most frequent and plentiful supplies of manure on the land. With this medicine, administered not in broken doses, as timid physicians recommend their nostrums, but the whole portion swallowed down at once, I have never known any rotation to fail. Grain crops may follow grain crops, and grass crops may follow grass crops, or *vice versa*, and all will find in the soil the very *special* ingredient that they require.

But it was stated above that, in my opinion, some crops exhaust more than others. By this I mean that some have a more pernicious and injurious effect on the land than others. I have no doubt that grain crops are more injurious than grass crops. And why so? It is not because the grass does not, in common with the grain, take up the nutriment of the soil, and thus impoverish it. The fact is, both are exhausters, whether to the same amount, I pretend not to determine. One thing, however, is certain, that land will continue to produce grass longer than grain: and the reason is a very obvious one; for as soon as you remove the grass, it makes an effort to recruit itself, and I have known it to succeed in doing so, to the amount of the first crop. The second crop then falling and decaying on the land contributes materially to the fertility of the soil, and in this way we may account for the fertilizing effects of the grass. The grain crop, however, being wholly removed, and making no effort to recover itself, must necessarily be a rapid exhauster.

But it will be objected, that by following nature's model, as so much lauded above, we shall defeat one great object of all cultivation, which is to supply our numerous wants. Nature, it will be said, has but one want, and her whole crops go to the supply of that one; whilst man has numerous wants, and therefore cannot be equally generous. To this I reply, that the farmer's *greatest* want is rich, productive land. His first care ought therefore to be to supply this want; and if he can but succeed in this, he will find no great difficulty in supplying all other reasonable wants. Fertile lands will fill his corn-crib, and plenty of corn will

not only make his hogs merry, but will diffuse an air of cheerfulness over the whole establishment. But here is the rub. After nature's law has been violated, and by frequent removals of the whole products, positive impoverishment has ensued, how is the land to be resuscitated? To this I reply again, that here is a case that is plainly beyond the reach of any rotation in cropping. It is, however, a matter of comfort, that land labors under but one single disease, and that is poverty. It is, however, highly infectious; for it is almost sure to communicate itself to the proprietor, and then it spreads through the whole family; and when the land, proprietor, and family are all down together, the case is really a bad one. But even in this event, discouraging as it may seem, there is a remedy. Swaim, with his panacea, and Brandreth, with his pills, have each pretended that he has discovered a remedy for all the "maladies that human nature is heir to." Now I pretend to no quackery in human diseases, but I do think I have found a specific for the only disease that afflicts the land; and this specific is not rotation, but enriching manures of some kind. How these manures are to be obtained, I shall not now, of course, attempt to explain. Every one acquainted with the circumstances with which he is surrounded, must judge of this matter for himself. I will, however, just remark, that whilst a deficiency exists in one point, there is commonly a superabundance at another; and that it requires but little skill so to concentrate one's resources as to make them most available.

After the above statement, the reader will not be surprised when I inform him that in my practice I rely but very little on any system of rotation whatever. In fact I rely scarcely any on this source, to keep up the fertility of my lands, much less to increase it. My main crop for market is hay, and every thing is conducted on my little farm to make this crop as large in amount, and as good in quality, as I can. The fields are, therefore, continued in grass as long as they will produce a fair crop. When the fields become so infested with greensward and other filth as materially to lessen the crop—which is uniformly the case on all the high lands in three years, and sometimes in two—they are then ploughed up, and a corn crop is resorted to, to cleanse them. Some time ago, when my lands were less fertile, one crop of corn was sufficient for this purpose. It now requires two, and these in immediate succession. My system of alternation therefore is, two crops of corn, one of oats, and three of grass; and this I adopt not with the view of improving or even keeping up the fertility of the lands, but simply because I consider it as the best course in reference to my main crop.

The reader will not also be surprised when I tell him, that I never tolerate any grazing in any field, or at any season of the year. I have seen the idea advanced, and that too by thrifty farmers, that grazing was beneficial to the lands. I will believe this when I am convinced that the right way to keep up strength is to take away all the sustenance by which it is maintained. No one pretends that the removal of a crop adds any thing to the fertility of land. But what is the difference whether it be removed by the cart, or by the capacious stomachs of cattle? But it will be said, that in the latter instance it is again dropped on the land. True, but these droppings are so dispersed, and at intervals so wide apart, that every one must see that they do but very little good. There is one event, and but one, in which I would approve of grazing, and that is where the farm is a large one, the grass abundant, and the market too remote to carry the crop there in any other way. But in this case, the animals should be penned every night, and thus the manure concentred and made available. But it will be said that the *hoof* is necessary to the solidity and compactness especially of light lands, to make them produce wheat. But I should think that the same, or even a greater amount of compactness, might be secured by a heavy roller, and thus save the fields from the severe scourge of the animal's tooth. A fall fallow, late in the season, will ordinarily secure the succeeding crop of corn from the depredations of worms. But my paper is again too long. I therefore merely throw out these few hints for the present. At some future time I may resume the subject. The probability is that I may prepare one or two more numbers, but at present I cannot say on what subjects. The fact is, the season of the year has now arrived when farmers ought to go to work, and I am much more ambitious for the fame of a *working* than of a *writing* farmer. J. H. TURNER.

CHOICE OF LANDS.

From the South Western Farmer.

Many are every day emigrating to our state, and we hope before long to see the tide increased. Many too of our present settlers are every year adding to their clearings—and spreading cultivation farther into the ancient woods. For the benefit of such we propose to give a series of articles on the choice of lands, and the marks by which good and inferior lands may be distinguished in our climate. We have been to a considerable extent over the country, and have had some experience in this matter, but we know there are many better acquainted than we are with the subject; and the chief good we hope our articles to accomplish is, to excite the attention and aid of such individuals to the matter.

The most certain and simple manner of judging of the qualities of lands is by the peculiar growth. With prairies, where this mode of course could not be practised, we have little acquaintance, and we know no certain rule for ascertaining the qualities of such lands except analysis. We will before long get the apparatus necessary for this, when we will endeavor to give more particular information on every branch of the subject. But upon timbered land every farmer knows that the liability to overflow in swamps—the adaptation to cultivation—the richness of the soil—and its fitness to carry particular crops,—may all be ascertained by inspecting the peculiar growth the land in a state of nature produces.

We will take the varieties of trees, &c. in alphabetical order, and to give more utility to our articles we will add remarks on the qualities of the particular kinds of timber.

Apple, wild crab.—Though occasionally found growing on dry spots, it generally denotes a cold, tenacious, poor soil, and one which will be too

wet in the spring for cultivation. It is most common on the borders of low wet prairies.

Ash.—A plentiful, large growth denotes very superior land. It is never found with us on poor land; and except on the best it is scattering and small. In swamps the ash, with the butt growing up for some distance much larger than the trunk higher up, and the inequality ending abruptly, is a certain mark of frequent overflow. The ash denotes good corn land, and we would suppose equally a mark of land adapted to small grain.

In this country we are without the white or swamp ash found at the north, and so much used in carriage making, &c. Our ash is not tough and hard like that, but has an open grain, and is among the most *brash* or *breakly* of our timbers. It is very dry and makes better fire wood when green than any other tree we have. Its ashes have also been found among the most valuable for lie. The ash lasts well exposed to the air, but soon rots when buried. In common with all the trees which have a large portion of their trunks sap, the ash can seldom be deadened so as to die the first year.

Beech denotes good second rate land with us, and is never found except on loose mellow soil, which may never produce the best, but is very reliable for certain crops.—It is sometimes found in swamps which overflow, but in none which do so often and to any depth. Beech, like the ash, lasts well in the air, but soon rots when buried. The tree is easily deadened by taking out a thin chip in circling it.

Box elder.—This is one of the semi-dwarfish trees, and grows only on rich ground. To find it spontaneously attaining any size, therefore, is a certain mark of a good soil. It will grow in overflowed land, however. Of the qualities of the timber we know little. Its bark and leaves are said to possess valuable medicinal qualities.

Cotton wood.—This is a tree which never attains its growth except on the richest soils, and is never found naturally on any other. Though generally found in swamps, it will occasionally be seen on uplands which are rich enough. It will grow on overflowed soil. The timber is light and porous, and of little value, though it makes tolerable fence rails, and when dry pretty good fire wood. It rots almost immediately in the ground. It is not easily deadened, except by firing at the roots, the first year.

Cherry.—The wild cherry common among us, never attains a size over a foot or two through, except on the best soil. It denotes too freedom from overflow when found in bottoms. It is easily deadened, and the wood is extremely lasting and valuable in any use.

Cypress is an unerring mark of low, overflowed swamp land. When cypress land is reclaimed, however, it is found to be mellow and productive, and the tree is easily deadened. Though soft and porous, cypress is a most valuable timber, splitting out easily into shingles, &c.—easily sawed into lumber—and either in the ground or in the air extremely lasting.

Cane.—To see the large high cane we once had so plentiful among us—attaining the height of 25 or 30 feet—is a certain mark of the best kind of soil. On poorer soils it will never attain its full growth. Overflows kill it. So that in swamps subject to overflow, it is seldom found at its full size. It takes some six or seven years for it to grow to full size, and unless the land has been exempt from overflow for that length of time, large cane will not be seen. It goes to seed at long intervals and then dies spontaneously. It is a variety of the same species as the bamboo. In another article we will give a history of its seeding and growth.

Dog-wood.—This is another tree of semi-dwarfish growth. It is never seen on the very poorest land. But from that which is thin to the richest it is found flourishing in all. To find it growing in swamps however denotes exemption from overflow. The tree is too small to make the timber worth notice.

Elm.—This tree will not grow over a foot or a foot and a half through, except on rich land. It will not grow on lands much subject to overflow. It is easily deadened. And the heart of the tree is extremely tough and lasting, both in or out of the ground. It is used by our wagon makers for the hubs of their wheels. Also, for the screws to our cotton presses. The bark of the slippery elm is well known to have valuable medicinal qualities. The wood however is not so tough as that of the red variety.

Gum.—The black gum grows indiscriminatingly, on thin and rich lands. Its superior size on rich lands however is a distinguishing mark. It is not easily deadened the first year; and the timber is of little value—being too tough to split and shrinking and cracking very much in seasoning. The sweet gum, of the size of 4 feet and over through, is a very common tree in our rich bottoms, and on poor land is seldom seen except of a small size. It is a difficult tree to deaden; and the timber is nearly worthless. It rapidly rots in any situation.

Hickory, of a small size, growing thickly or predominating, denotes a good soil, though shallow. Large sized trees are found occasionally on rich and deep lands. The common kinds are seldom found in overflowed lands—but a variety with rough scaly bark found in swamps is a certain mark of inundation. The timber is too well known to need description. It is not lasting, and soon rots in the ground. The hickory to be deadened the first year must be chopped round entirely through the sap; unless this is done it will continue vigorous to the second summer.

Holly.—This tree is a certain mark of good land. It is semi-dwarfish—difficult to be deadened—and loves swamps which are not much overflowed. The timber is very white and close, and is used by cabinet makers for inlaying.

Haw—black.—This shrub denotes rather a thin soil, never being found on our richest. It grows only in dry spots. Of the *red* there are two kinds, one with many thorns and a fruit much larger than the other—nearly the size and shape of the crab apple. This kind grows only on high dry spots, denoting a poor soil. The other has the fruit of a smaller size in clusters, and sweeter tasted, and the tree grows taller and is freer of thorns. This kind loves swamps and low places, and generally denotes a rich soil though wet and tenacious.

Hornbeam, or iron wood.—This is another semi-dwarf, and denotes, like the beech, good second rate land—never being found on either the richest or the poorest.

REJOINDER UPON THE SUBJECT OF MANURES, &c.

To the Editor of the Farmers' Register.

Sandy Point, May 15, 1842.

Please to afford me a small space on your pages to reply to the remarks of the Rev. Mr. Turner, on my strictures on his anonymous essay on manures, &c., which appeared in your January number. From the general tenor and train of ridicule in his remarks, he doubtless intended that they should act as an extinguisher, and sweep all such ephemera from his path in future, even when he chooses to write anonymously. I have not failed, Mr. Editor, to appreciate the agricultural writings of Mr. Turner, and to pay to his known and subscribed opinions a respectful deference.

In his remarks on my strictures relative to his mode of managing stable manures, he says, "By what management can manure be most rapidly increased? Is it by daily throwing it out in small quantities, &c.?" In reply to which I here repeat, as the result of my own experience, and that of the majority of the most intelligent and experienced farmers and horse owners, that, from a due and prudent regard to the comfort and health of the horse, manure ought *never* to be allowed to accumulate in the stable beyond 24 hours, and if oftener cleaned out the better; and I do assert that, by cleaning out the stable daily, a greater amount of manure, and that of a better quality, can be made, than by allowing it to accumulate in the stable. Were I asked "what would be the surest mode of obtaining *fire-fanged* manure?" I would unhesitatingly reply, "allow it to accumulate in the stable;" and foul stables are well known to excite and aggravate many of the diseases to which the horse in his domestic state is liable. It is rather a singular doctrine for the reverend gentleman to advocate and recommend—the permitting of a *known* evil, that (doubtful) good may result. "An ounce of prevention is worth a pound of cure."

In the printed report of the "Proceedings of the Henrico Agricultural Society, for October, 1841," I see it stated by Mr. Turner that, from 21 head of horses, mules, cattle, and a considerable number of hogs, he had manured the preceding season 10 acres of land, at the rate of 25 cart loads per acre, (as gathered from a preceding portion of that report.) Now I can tell him that, on this estate, with an equal number of mixed stock and the mode of management here pursued, not less than one-third *more* than that quantity of land has this season been manured; and that from all sources, and these none other than domestic, since the month of November last, not less than 180 acres of land have been heavily top-dressed.

The stables for the horses and oxen occupy each one side of a large square, in the middle of which is a place of deposite for the manure, deepened in the centre, having a stiff and retentive clay bottom, gradually rising to its outer edges, around which there is a sufficient bank raised, and so formed as at all times to afford a dry and comfortable footpath all around the square. Both stables are thoroughly cleaned and swept out every day, and the floors plentifully sprinkled with ground gypsum, the probable benefit likely to result from the daily application and consequent mixture of which with the manure need not be here described. A regular and large supply of fresh litter in the shape of clean and dry wheat straw, and none other is used, is also daily applied. Amongst this manure no hogs are permitted to root, nor is the manure allowed to accumulate to any injurious extent, being hauled out as frequently as opportunity offers, and applied as a top-dressing to clover, at any period of the year, and always with decided advantages; and it is indeed a very rare circumstance to find amongst the manure any degree of fire-fanging.

Mr. Turner very pointedly refers to "the very large quantities of marl and burnt shells" used on this estate, but I think with an incorrect inference. The proprietor of this estate, his manager and many others in this neighborhood, entertain the perhaps singular belief, that putrescent manures can only be applied with permanent advantage on soils that are either naturally or artificially rendered calcareous. If there is error or fault in this belief, Mr. Editor, you have here, amongst your other *little* peccadilloes, a heavy account to answer for. I will here, however, aid you with one of *many* proofs of the correctness of the positions which you laid down as to the true operation of calcareous matters when applied to the soil. In the spring of 1840, a portion of land on this estate had a heavy application of putrescent manure. About 200 hhds. of shells were applied to one side of this manured land, the remainder then and now remaining unlimed. On the whole, corn was planted, followed by wheat and clover, to both of which crops the benefits from the lime were very obvious. This spring that portion not limed was again heavily top-dressed, and none applied to that which had been limed. The whole was grazed partially by sheep until the beginning of this month. From the limed portion we are now daily cutting a very good growth of clover, for the purpose of soiling, [feeding green,] while on that which had not been limed, but which had the benefit of an extra dressing of putrescent manures, there are only a few straggling plants of red clover to be found, with a tolerably close and low growth of white clover and natural grasses. Were a person to pass over these portions of land blindfolded, he could from the difference of growth tell when he came to the dividing line between the limed and unlimed land.

In reply to Mr. Turner's "set-off," to my objection to pen-feeding cattle, I will take the liberty of stating, that if he has "never been able to secure health and cleanliness by any other mode, "than by pen feeding, he has never properly practised stall feeding. And the case which he instances in his effort to fatten one of his steers is a proof of it; for no animal that is properly stalled and taken care of can by any possibility other than carelessness become covered by his own filth. Both modes I have seen fully tested, and under circumstances as favorable for pen feeding as Mr. Turner has adduced. The benefits of stall over pen feeding, for all animals which are required to labor daily, are I think very obvious. On this estate, all of the working oxen have been stalled when out of yoke, since the beginning of March last, when their stables were ready for their accommodation. And I am fully warranted in saying, that from their improved condition and efficiency for labor since that time, one fourth is added to their value, and of a

morning, as to any of their filth which adheres to them, Mr. Turner might pass his cambric handkerchief over both their flanks and sides without materially soiling it. Out of 30 oxen which have been regularly at work for the past ten months, several good beeves could *now* be selected, with skins as sleek and clean as could be desired; and I may also add, that these 30 oxen, with the aid of 4 others occasionally to relieve the weaker individuals, have executed all of the spring labor formerly performed by a number of animals varying from 42 to 48; and not a single instance has occurred of a steer failing to perform the daily labor required of him.

I now come to that portion of the reverend gentleman's remarks where he became "at once fully convinced that Mr. Nicol did not know against whom he was hurling his shafts." Let me here, Mr. Editor, compliment his sagacity in becoming "convinced" that I did not know who was the writer of an *anonymous* essay appearing in your pages. I had no intention of attacking his "strong forte," or his hog management, further than was implied in his mode of making them manure raisers, as gathered from his anonymous essay. Suited to his peculiar circumstances, his hog management, for aught I know, may be the very acme of perfection, and in his opinion I doubt not it is so. The price which he obtained for his eight months old boar was really good. But was it sold to the butcher or fancy hog breeder?

As to Mr. Turner's "one word more," I will not give insult, by believing that any of his intelligent neighbors would be guilty of so much rudeness as *to laugh* at any individual, however humble his station, or homely his mode of expressing himself, who would *honestly* express a dissent from the anonymous opinion of Mr. Turner or any other person.

The concluding passages of the remarks require no comment; their evident drift and intention is sufficiently plain; and with an apology for occupying so much more of your space than I had intended, I am, Mr. Editor, your humble servant,

A. Nicol.

It is unpleasant to us at all times to have controversy, on agricultural subjects, conducted between any of our correspondents in any other than the kindest feeling towards each other, and with the single object of eliciting truth by discussion. It has therefore been to us a subject of regret, that any asperity, or expressions that could give the slightest offence, should have found place in this controversy between two persons, to whose contributions we attach high value. Each, in turn, has thought himself aggrieved, and claimed the right to reply; and each has now been permitted to "shoot his bolt," or to "have the floor," in reply to the other's strictures, and though not as fully as he desired, to the full extent that we deemed admissible and proper. And now this controversy must stop here, or at least as to any thing farther that would apply to the person or the particular opinions of the opposite party. We have taken the liberty to prune from the articles, on both sides, some passages which were too pungent. For this we crave the pardon of both writers, and fear we shall have the thanks of neither; usually happens to the unlucky editor in such cases, we may have somewhat offended both the opposite parties, not only by what we have admitted, but also by what we have refused to admit. It is scarcely necessary to add, that the communications of both these highly respected correspondents, in support of their own opinions and practices, without too pointed condemnation of others, and whether on the points now in question, on any others, will be always most welcome to the pages of the Farmers' Register. —Ed. F. R.

WIND PUMP, FOR KEEPING LOW MARL PITS FREE FROM WATER.

To the Editor of the Farmers' Register.

I met with a gentleman from Eastern Virginia, more than a year ago, in the steamboat, who professed to be a farmer, and a subscriber to the Farmers' Register. He spoke of great improvements made by the use of marl, but said, in Mathews county, his residence, though marl had been found in many places, the land was so low and so flat, and water rose so near the surface, the use of it had not been attempted. I told him that I knew a farmer in the low lands of Talbot county, Md., who, under the disadvantages he mentioned, was working a pit much to his profit; and I promised, at his request, to make a communication on this matter in the Register.

Mr. John Dawson, the proprietor, informed me that after a painful search he found a bed of marl, on the banks of St. Michael's river, eight feet below the surface, and on a line with the river, and, upon removing the superincumbent earth, much water rose in the pit, which he drew off by means of a sweep and bucket, and worked in this way for some time. An uncommon high tide overflowed the banks of the river, and filled his pit. To clear it by the means he had been using, he deemed hopeless. Some person recommended to him to apply to Mr. O. Hussey, a skilful and ingenious mechanic of Baltimore, who constructed for him a pump, worked by the wind, which drew off the water. He still continues to use it, and the water now is no obstruction to his operations. By means of an inclined road he now gets marl with much facility. I saw the contrivance and was much pleased with it, and have no doubt but in Mathews, or in any other level country where the water cannot be drawn off by ditching, it might be advantageously used.

The cost of the pump, with the appendages, was one hundred dollars. If it should be deemed too expensive for one farm, by selecting a convenient spot it might serve for two or more.

I have forgotten the gentleman's name to whom

I have referred. If this shall come under his observation, he will see that, though the performance has been delayed, the promise was not forgotten.

WM. CARMICHAEL.

Wye, Queen Ann's co., Md., April 30, 1842.

NEW AGRICULTURAL SOCIETIES.

Two Agricultural Societies have recently been organized, one in the county of Prince George, and the other in King William, and both upon the *working* plan, recommended in the last December number of the Farmers' Register. The form of constitution there published, with a few changes of unimportant details, has been adopted by both these societies, and therefore it is unnecessary to publish the forms of constitution actually adopted. The plan requires that every member shall *do something* in furtherance of the objects of the institution, by accurately conducting and carefully noting, and reporting some one or more agricultural experiments each year. And if this be but done, the most unpretending labors of a society in any one year will serve to establish some useful truths; to indicate something of new practice, and beneficial and profitable to be performed; or something of old, useless or injurious, to be omitted and avoided; and this will be more than is generally done by other agricultural societies. But even the best devised plan of constitution and of operations for a society alone, will not be sufficient to make a society useful, unless the requirements of the plan be truly and faithfully obeyed by the members. We earnestly hope that there may be no such deficiency in these two societies; and they have our hearty and zealous wishes that their usefulnes and their success may entirely fulfil their design and objects.

REMARKS ON THE CULTURE OF INDIAN CORN, IN REPLY TO THE EDITOR OF THE CULTIVATOR.

From the Southern Agriculturist.

Dear sir.—In looking over the first and second volumes of the Cultivator, my attention was particularly attracted by the following editorial remarks on the subject of Indian corn and its culture, namely: "The roots grow to as great a length as the stalks;" and "In corn ground we think six to nine inches a suitable depth" in ploughing, as "the roots will strike fully to this depth if there is food for them."

Now, as there could be nothing more absurd than to maintain that a plant, five to ten feet high, has roots as long as itself, and that these roots go down perpendicularly, and yet reach no lower than eight or nine inches below the surface; the conclusion is obvious, that the editor believed in the horizontal distribution of the roots of corn as a general rule. Having had no opportunity of ascertaining, from personal observations, what the fact on this point is, in the soil and climate of that latitude, I notice this opinion of the Cultivator, not for the purpose of denying its correctness in so far as it may apply to that section of the union; but to show, that however well founded there, it is not altogether in accordance with facts here. And with this view, I shall state the general results of examinations of this plant, repeatedly made, in order to satisfy my own mind on this point.

It is not intended here to deny the existence of horizontal roots to the corn plant, (a fact with which every planter is no doubt familiar); but to call attention to the no less important fact, that these roots, however indispensable may be their functions, are not the principal in size, but are given off from other and much larger roots, which go down perpendicularly or nearly so, to a depth under favorable circumstances of several feet.

The plants first examined grew in a very light sandy soil, incumbent on a loose subsoil of yellow and white sand many feet deep. Here, upon carefully removing the earth to the depth of two feet, all the large roots were found running down perpendicularly; or at least so nearly so, as to be embraced in a circle of eighteen or twenty inches diameter, at a depth of two feet below the surface. More surprised at first, than satisfied with this discovery, I examined a number of other plants in the same manner, but with the same result; and was, of course, compelled to abandon the opinion previously entertained, that the main roots of the corn plant were all horizontal. These plants averaged about twenty-five perpendicular roots, some of which were traced two feet nine inches, when they were snapped off; and, upon comparing their diameter where broken off with that a foot above this point, it was evident they must have penetrated at least a foot deeper, making their entire length not less than three and a half to four feet. It should be remarked, however, that occasionally one of these large roots was found so bent in its course, as to run parallel with the surface: and further, that in one or two plants the majority of the roots diverged at such an angle, that they could not be strictly considered either perpendicular or horizontal. But these were plainly mere exceptions to the general rule. With regard to the horizontal or lateral roots, it was observed that the degree of their developement seemed to depend mainly on the condition of the soil, (properly so called,) and the season: Where the former was poor and the latter dry, but few of them, apparently, exceeded two or three inches in length, while many were much shorter. On the other hand, where the soil had been made very rich by high manuring, more especially if a wet season concurred, these roots were very much increased, not only in numbers but in all their dimensions, a large proportion of them extending from one to two feet or more from the stalk. All other things being the same then, these roots (the lateral) would seem to be developed on the one hand, in proportion to the fertility of the soil; and on the other, to the degree of humidity of the season; attaining their

utmost size under a concurrence of wet seasons and high manuring, and their least under the opposite contingency. There appear to be good grounds for believing, too, that wherever circumstances favor the growth of one of these classes of roots, that of the other is correspondingly retarded.

With a view to ascertain whether or not this disposition of the roots of the corn plant were affected by the texture of the soil and subsoil, several plants were next examined, growing in a close and heavy soil, based on a stiff subsoil, consisting principally of clay with some sand. But here, also, the same law was found operating in giving a downward tendency to the main roots. They were observed, however, to be more numerous, and to reach an average depth of only two feet, their progress downwards, being no doubt obstructed by the resisting quality of the subsoil. The horizontal roots, though of smaller diameter than the perpendicular, were so much more developed than in the former case, especially when favored by a moist and mellow soil, as to traverse and occupy the entire intervals (a space of five feet) between the rows.

The results of the above examinations certainly go to show, then, that the opinion of the Cultivator is not in strict harmony with facts, at least in this locality: that, in short, the principal roots of the plant under consideration, so far from penetrating only eight or nine inches below the surface, actually reach a depth of several feet; while the horizontal, which that journal seems to regard as the principal roots, are, in point of fact, smaller (though often longer) ones given off from the former. It has been seen, moreover, that the relative dimensions of these two sets or classes of roots are not always the same; their respective developements depending, as they do, on the controlling influence of the several ever varying causes enumerated.

We cannot reflect on the foregoing facts without at once perceiving, and, in some degree, appreciating their practical bearing. Nor can any one, acquainted with the habits of this plant, fail to discover the wise adaptation of means to the end displayed in the number and position of its larger roots. One happy and very obvious effect of this arrangement is, a degree of exemption from the effects of drought, which could not be enjoyed under any other. Hence it is that corn, although so susceptible of injury from this cause, does not suffer more from it. For it cannot be questioned that, with its present physiological constitution unchanged, the harm it would sustain would be much greater were its roots horizontally placed, and of course near the surface. Indeed, this fancied position of its roots can never sufficiently account for the readiness with which this plant suffers from drought. This phenomenon is clearly referable to nothing else than the organization of the entire plant itself. The most obvious of its features—its size, the well-known porous structure of its stock and leaves—its rapid foliar transpiration, &c., sufficiently indicate the need of a quantity of sap both absolutely and relatively large. Now, as water is essential to the formation of sap, and constitutes such a large proportion of it, it would seem evident that this plant, which contains so much sap, must require a corresponding quantity of water, and must suffer sooner for the want of it, than if its relative portion of sap were much less.

Indulge me here, Mr. Editor, with a remark or two on this point relatively to the cotton plant. Its capability of resisting drought has been attributed, in a published communication, to its tap-root. This, it is supposed, by penetrating to a great depth, furnishes a supply of moisture sufficient to enable it to withstand a drought, by which corn would be seriously injured if not destroyed. In order to determine the truth in this matter, I have pulled up and examined a great many plants after the 15th or 20th of July; but have found a large proportion of them with no tap-root at all: while in others this root had either assumed a lateral direction, or had become so diminutive in size, and inferior to the lateral, as to be evidently incapable of the effect above ascribed to it. Yet these plants were as little affected by drought and as productive as the tap-rooted. Now if the latter resist drought by virtue of their tap-roots, by virtue of what do the non-tap-rooted plants resist it? Were it this root alone that conferred immunity from the effects of a dry season, one might expect during such a time easily to distingnish between them while growing; but this, it is believed, cannot be done; and it is more than probable that the relation of this plant to the season is as little controlled by its tap-root as that of the corn plant is by its horizontal roots. The former, whatever may be its degree of succulency, becomes gradually more and more woody, until at maturity, it acquires the closeness of texture and hardness of many shrubs. While, on the other hand, the stalk of the latter is more or less occupied by a pith so filled with sap that it may be wrung from it almost as water from a saturated sponge. Were equal portions, by bulk, of cotton and corn-stalk, at the same period of their growth, deprived of their sap, the quantity from the former would doubtless be much less than that from the latter: for the very obvious reason, that the dense and compact structure of the one is incompatible with that capacity for sap existing in the very light and porous pith of the other. Hence it would seem safe to conclude, that cotton, containing, as it does, less sap, requires less moisture than corn; and is, of course, better able to sustain itself during drought, even supposing the relative activity of the leaves to be the same in both plants. This opinion is corroborated by the effects of the great drought of 1839 on some of our forest trees situated in certain high and thirsty localities. The oaks, so far as I observed, exhibited no evident symptoms of injury, while the pines growing among them lost, in some instances, a moiety of their leaves. Here then the case of cotton and corn is reversed; the tap-rooted plant suffering least in one case, and most in the other. This, it is conceived, can only be explained by reference to a difference of organization; the result of which was, that the pine, though fortified by an immense tap-root, became the earlier and greater sufferer. * * * * * * *

L. Reeve Sams, M. D.

INTERESTING TO COTTON GROWERS.

From the Memphis Enquirer.

Panola Cy. (Miss.) Jan. 26, 1841.

Mr. Editor,—It is usual for cotton growers to sun their cotton as they gather it, and then gin it as early as possible. This, according to my judgment and experience, is clearly wrong. Cotton should never be sunned, unless it be such as has been gathered quite wet with rain; nor should it be ginned until it has been heated.

Heat diffuses oil, and we know there is a large quantity in cotton-seed. Now, sir, put it together as you gather it, both morning and evening, and there is sufficient moisture to make it heat. This being the case, the oil in the seed is diffused throughout the lint—for it cannot evaporate. When it remains in this situation a sufficient length of time to spoil the seed, the cotton should then be thrown up and cooled. Care should be taken not to let it turn blue:—this, however, is not so easily done as you might suppose.

The process of turning over and throwing up will likely have to be repeated two or three times before the seed are entirely spoiled. The trouble of overturning and tossing it up in the cotton or gin house is not greater than sunning it on a scaffold. By this process you gain the weight of the oil which is diffused throughout the lint, and which gives the cotton the oily gold color which is desirable, and also that elasticity and adhesive quality, like wool, which never fails to enhance its value.

But, sir, there are other advantages growing out of this operation: the gin will pick at least one-sixth faster, and clean the seed much cleaner when the cotton has thus been compressed together; and instead of cutting off short particles, as is always the case when the cotton is open and fresh, the saws take it off in large flakes, thereby making the staple longer and stronger.

Every farmer knows that his early cotton outweighs, and has better staple than his late cotton; and he also knows that the earlier it is gathered after it opens the better. Now, sir, these facts show the correctness of my theory; for exposure to the sun and rains evaporates the oil from the seed and makes the lint short and light.

Farmers should secure in dry weather and from evening pickings, in a house to itself, or a portion of the gin, sufficient of dry good cotton, to make seed, but the balance of their crop they should be sure to subject to the process of heating and cooling in the shade. It is said that the British East India cotton is vastly inferior to ours at present. If we can make our cotton still better, the danger from that quarter will be lessened.

ASPARAGUS.

From the British Gardener's Chronicle.

A few weeks since, we reported briefly the substance of a paper upon the cultivation of asparagus in the north of Spain, which was communicated to the Horticultural Society by Captain Churchill, of the Royal Marines. This gallant officer was at St. Sebastian during its occupation by General Evans; and he profited by such leisure as his military duties afforded him, to make himself acquainted with the natural history and horticulture of Guipuscoa. We might content ourselves with merely referring the many inquirers who want to know how to grow asparagus well, to the report just alluded to; but in our opinion it is much too important to be passed with so little attention.

Asparagus is probably the vegetable most generally admired and most seldom well cultivated; it is only here and there that it is large, tender, and delicate. In country gardens it is small, green, and strong; in the London market it is long, white, hard, and tough—to the eye attractive enough, but to the taste more like bleached timber than an esculent. Indeed, we have never been able to comprehend the reason why, in this our age of improvement, some ingenious turner has not produced imitation sticks, which might be tipped with half an inch of eatable asparagus, and thus spare the necessity of cooking four-fifths of the stuff that is brought to a London table. Covent Garden asparagus is assuredly the worst in Europe. For this reason, when really fine asparagus is met with, people think it must be some peculiar sort—obtain the roots from Vienna, Berlin, Hamburgh, Battersea, or Deptford, and then, when they find them producing heads identical with what they had before, lay the blame to the seedsman, or the soil, or the climate, or any thing rather than their own want of skill. There is but one sort of asparagus, be its name what it may; all the difference consists in its cultivation.

Captain Churchill says the Guipuscoan asparagus measures from three to six and more inches in circumference. How this is obtained, his excellent account leaves no room to doubt.

Asparagus is a plant found naturally on the beach of various parts of the coast of Europe, where it is covered by the drifting sand, and watered by salt water at high tides. Sand and salt water occasionally may, therefore, be regarded as indispensable conditions for maintaining it in health. How seldom is this thought of! It, however, explains in part the excellence of St. Sebastian asparagus.

It seems that at the mouth of the Urumea is a narrow slip of land, about three feet above high-water mark, consisting of alluvial soil and the wearing away of sandstone hills, at whose foot it is placed. This is the asparagus ground of St. Sebastian. Beds are formed five feet wide, without any previous preparation except digging and raking. In March the seed is sown in two drills, about two inches deep, and 18 inches from the alleys, thus leaving a space of two feet between the drills. The rows run invariably E. and W.—doubtless in order that the plants may shade the ground during the heats of summer. When the seedlings are about six inches high, they are thinned to something more than a foot apart. Water is conducted once a day among the alleys and over the beds, so as to give the seedling an abundant and constant supply of fluid during the season of their growth. This is the cultivation during the first year.

The second year, in the month of March, the beds are covered with three or four inches of fresh night soil from the reservoirs of the town; it remains on them during the summer, and is lightly dug in during the succeeding autumn; the operation of irrigation being continued as during the

first season. This excessive stimulus, and the abundant room the plants have to grow in, must necessarily make them extremely vigorous, and prepare them for the production of gigantic sprouts.

In the third spring, the asparagus is fit to cut. Doubtless all its energies are developed by the digging in of the manure in the autumn of the second year; and when it does begin to sprout, it finds its roots in contact with a soil of inexhaustible fertility. Previously, however, to the cutting, each bed is covered in the course of March very lightly with dead leaves, to the depth of about eight inches; and the cutting does not commence till the plants peep through this covering, when it is carefully removed from the stems, in order that the finest only may be cut, which are rendered white by their leafy covering, and succulent by the excessive richness of the soil.

In the autumn of the third year, after the first cutting, the leaves are removed, and the beds again dressed with fresh night-soil as before; and these operations are repeated year after year. In addition to this, the beds are half under salt water annually at spring tides.

Let any one compare the mode of culture with ours, and there will be no room for wondering at the difference in the result. The Spaniards use a light sandy soil; we are content with any thing short of clay. They irrigate; we trust to our rainy climate. They know the value of salt water to a sea coast plant; we take no means to imitate nature in this respect. They dress their beds with the most powerful of all manures; we are contented with the black residuum of a cucumber frame, which is comparatively a *caput mortuum*. Finally, they throw leaves lightly over their beds, by which means they expose the young sprouts to the least amount of resistance, and force them onward by the warmth collected from the sun by such beds of leaves; we, on the other hand, compel the asparagus to struggle through solid earth, capable in the smallest possible degree of absorbing warmth during the day—but, on the other hand, ready to part with its heat again at night to the greatest possible amount.

Can any one wonder, then, at the poor results obtained by our manner of cultivation?—or that some gardener should now and then astonish his neighbors by producing asparagus which we call giant, but which at St. Sebastian would be called second rate?

THE ARTESIAN WELL OF GRENOBLE.

From the Mining Journal.

At Grenoble, in the vicinity of the French capital, it was considered advisable some years ago to endeavor to procure good water by means of an Artesian well. M. Mulot d'Epinay was the engineer to whom the task was entrusted. On the 31st of December, 1836, the bore had been carried, after immense labor, to the depth of 383 metres, (a metre is 3 feet and 2-10ths English.) The soil was a clay, very hard and compact. In the month of June, 1839, the bore had reached the depth of 466 metres, and the soil was still a bed of clay, though a variety of strata had been previously passed. M. Mulot kept a regular journal of observations relative to the soils and strata penetrated, and the temperature at different depths. This record will be valuable when published. At length, after a task of seven years one month and twenty-six days' duration, M. Mulot was rewarded by a degree of success proportioned to the time and trouble expended. Water was not only found, but found under such circumstances, and in such quantities, as will cause the well to be one of the most useful works as well as one of the greatest marvels of artistical ingenuity in France. The fluid burst out in a perfect torrent, rising to the surface of the bore to the amount of nearly three cubic metres in a minute, or 180 metres in an hour, and 4320 metres in the twenty-four hours. Such is the force with which it flows up the shaft, that it mounts more than thirty-two English feet above the surface of the ground. Mr. Hemery, director of roads and bridges, has calculated that the force of ascension of the water, at the bottom of the shaft, exceeds, by fifty times, the force with which water rises in a vacuated tube of thirty-three feet. The orifice of the well is fifty-five centimetres (about one foot eight inches) in diameter, and at the bottom it is eighteen centimetres in diameter. The shaft is in all 547 metres (or 1630 French feet) in depth, and the sides are strongly plated with iron to a depth of 539 metres. The dome of the Invalids, which has an elevation of 300 feet above the ground, is thus only about a fifth of the perpendicular measurement of the Artesian well of Grenoble.

Three times, during the operation, did the shaft give way, but the indefatigable engineer was not daunted, and at last he has had his reward. The water, which the well pours fourth incessantly, has converted one of the neighboring streets into a river, but the workmen are at present employed in forming a channel for its proper conveyance from the spot. As might be expected, the fluid was at first mixed with sand and earth, and continued to be so for some time. It is perfectly sweet, however, and had no odor of a disagreeable kind, or any other deteriorating qualities. It is of such a temperature, that there is an obvious smoke arising from it when it reaches the surface. This is a feature not likely to continue, and indeed easily removeable before use. The whole cost of this great work of art to the city of Paris is said to have been 160,000 francs. The perseverance in this labor for such a period of deferred success, is to be ascribed to the confidence resulting from modern geological discoveries; and the value of these is most splendidly shown by the success attained. By an ingenious contrivance, M. Mulot has been able to raise large quantities of sand from the bottom of the well; thus clearing the water more rapidly, and also adding very considerably to its force and volume. This removal of the sand has been attended with curious consequences in more respects than one. After ceasing, in a great measure, to throw up sand, the well has begun to throw up shells and petrifactions of various kinds, the debris of a former world. The success of the operations at Grenoble has also induced engineers to make similar attempts in other quarters. One is begun on a large scale at Vienna.

EXTRACTS FROM A REPORT TO THE STATE BOARD OF AGRICULTURE.

By Edmund F. Noel, of Essex county, Va.

ON LIVE-STOCK AND FRUITS.

The Virginia Board of Agriculture, at their first meeting in December last, agreed upon certain queries to be propounded to the most intelligent and experienced farmers and planters in the state, stating that no one individual would be expected to reply to all, but only such as he should best understand. As one of the circulars of the Board containing the queries has been addressed to me, I will proceed to cast in my mite, hoping others may do the same, and that much valuable and useful information may be obtained.

8th Division of queries.—Live-stock.

Our breed of cattle, with few exceptions, is mostly of the native breed. Mr. Coke, of Norfolk, England, sent to Messrs. Patterson and Caton, of Baltimore, some Devon cattle in 1817, and in 1825 I purchased a pair of calves of Mr. Caton at $250. I crossed them upon my cattle of the native breed. The cross I thought was superior to either breed. Many of the oxen lived and worked for me more than ten years, and performed well. Along with them the most of the time half Durham oxen worked: the cartmen were of opinion the half Devon oxen were much the best.

Durham cattle.—In 1828 I purchased of Col. J. H. Powel a Durham short-horn male calf, at $300, and crossed upon my cattle of the native breed. The cross was larger and finer than the Devon cross; but whether they were larger and finer in proportion to the food consumed, I do not know. The animal I bred from was probably superior to most of the Durham cattle. His sire and dam were imported from England by Col. Powel; and he bred from his sire, instead of other males imported by him. His dam, with twenty other Durham cattle, was exhibited at the Pennsylvania Agricultural Society the year before I got the calf, and by the society was pronounced second best. Col. Powel afterwards raised a male calf from her by the same sire, for his own use; which animal he afterwards sold to a gentleman in Kentucky, near Lexington, for $1000. I make this statement of facts so as not to mislead any person. An inferior animal of the Durham breed might have given a different result. I have had a chance of seeing a great many fine cattle in different parts of the United States; and, my life being entirely that of a farmer, I have taken much pleasure in looking at them. Many years past I saw the Devon cattle then in the neighborhood of Baltimore. Some years after I saw, near Philadelphia, Col. Powel's large stock of Durham cattle, a few days before his great cattle sale. Since which I have had a chance of seeing in Kentucky and Missouri a number of fine cattle of different breeds and crosses, but I have never seen finer oxen than I have seen in Mississippi, in the Choctaw purchase, of the native breed. I became a planter in that part of the state soon after its settlement, and I have spent many winters there. For some years after its settlement, nearly all the cotton was carried to market in ox-wagons, and during the time of delivery, it was nothing uncommon to see in a day several hundred oxen on the road leading to Manchester, (now Yazoo city,) and no person could behold them without admiring their size and beauty. Grass was then plenty, and they were fat the year round. The great error in lower Virginia is that of keeping an overstock of animals. Under such management no breed will be an improved breed long, nor an improved cross.

Sheep.—Our breed of sheep, like our breed of cattle, with few exceptions, is mostly of the native breed. Fine-wool sheep with us will not answer; we want coarse wool to manufacture in our families; and under our system fine wool is filled with trash, and will not do for market.

Bakewell sheep—called Bakewell after the fabricator of the breed, Dishley after his farm, and New Leicester after the part of the country in which he lives. This breed is hornless, white face and legs, wool long, just such as we want in our families for coarse fabrics; constitution tender; remarkably docile, more so than any sheep I have ever seen. For beautiful form and great propensity to fatten this breed is supposed to be unequalled. Numbers of this breed of sheep have been imported into the United States since our last war, and they have taken nearly all the premiums offered for coarse-wool sheep; lots of them have been slaughtered in our large towns to the north, averaging over twenty pounds of tallow per head, and small lots of them have averaged over thirty pounds per head. For a number of years I have had only half Bakewell sheep upon my farm, a cross on the native breed, with which I am very much pleased. But I have occasionally had a few pure Bakewell sheep, the cost of which $20 per head. But they did not appear to do as well as the half breed; they were more subject to disease, and not disposed to ramble over the farm as much in search of food. But where food is plenty, and they are well taken care of during the winter, I should suppose the pure breed greatly to be preferred.

Southdown sheep.—Hornless, speckled face and legs, wool short and fine, of a hardy constitution. Many years past I purchased two ewes of this breed, then with lamb, at $30 each. I was induced to make this purchase from the high character given to this breed of sheep, and particularly this family of them, by gentlemen in Philadelphia. See American Husbandman and the American Farmer, vol. 7, page 361. I am thus particular, lest it may be thought this family of Southdowns were not of the pure breed. I found them to be a hardy breed of sheep, with no greater propensity to fatten than the common sheep of our country, and their mutton no better; the quantity of wool very small, about what English writers state it to be in England, two and a half pounds per fleece. This breed of sheep proved the most unprofitable of any I ever had upon my farm.

Hogs.—Our hogs have been crossed by various breeds. I have myself purchased some from Connecticut, New York and Pennsylvania. Those I got from Pennsylvania I got of Mr. Barnitz. This breed was the best I ever had upon my farm; they were not of the breed described in the American Farmer, vol. 13, page 279, but a cross upon that breed, which he afterwards made. I cannot now lay my hand upon his letter, but, as well as I now recollect, he stated it to be a cross of the Chinese and Chichester breeds. Some years past

I got of Mr. Bement, of Albany, New York, a pair of Berkshire pigs. They did not come up to my expectation; their descendants were still worse; and, supposing they were in a state of degeneracy, from breeding in-and-in too closely, I determined to give them a cross, which was done with the following family of Berkshires.—(New York Cultivator, vol. 5, page 138.)

Berkshire pigs.—Messrs. Brentnall, of Canterbury, Orange, who have a stock of these pigs, from original importation, cite the following as the weights to which they have attained, at the ages noted: one, under two years old, weighed 652 lbs., one four years old, 702 lbs., one three years old 780 lbs., two eighteen months old 432 and 432½ lbs.," &c. The animals of this cross are now nearly grown, and are better than the Bement was, but nothing to justify what has been published in this country respecting the breed.

* * * * * *

13th Division of queries.—"Miscellaneous observations and statements of any thing of interest, not included in any query."

Under this division I will make some remarks on fruits, &c., without any arrangement of matter, and confine them to apples, pears, peaches and grapes. The number of different varieties of fruits now offered for sale in the United States is very great—of apples, pears, peaches and grapes, several hundred varieties. When such vast numbers are to be disposed of to inexperienced farmers, and scattered over the country, it is much to be regretted, there are but few which are of superior quality; and a few of these, judiciously selected, would supply the wants of a private family. Our apples and peaches are mostly of those kinds cultivated by our fathers, for the purpose of making spirits for market, which was common in those days. Our orchards at present have an unsightly appearance. The influence of the temperance society is very injurious to orchards. It is always on the ebb or flood; one year the caterpillars are suffered to eat up the orchard; another, the orchard is trimmed up and worked; one year the stills are pulled down; another, they are rebuilt, and the harvest gathered in with a shout. To avoid the too common error of the world, of telling others what they ought to do, and doing nothing themselves, I will tell what I have done, and the errors and difficulties I have had to encounter, that others may avoid them. In early life I purchased the plantation on which I now live. It had been held for a number of years as a life estate, and many parts tenanted out; and was just such a place as one would have expected to see. Some half a dozen apple trees, and a few old peach trees above the reach of cows, were nearly all the fruit trees upon the farm. Wishing a good orchard, I purchased 300 apple trees, of an individual in this part of the country, and planted them out. Shortly after which I purchased an excellent treatise on fruit trees, that had just been published, by Mr. Coxe of Burlington, New Jersey, with descriptions of the finest varieties of fruits, illustrated by cuts of two hundred varieties, of the natural size; and having moved from that part of the farm where I had planted the first orchard, to a more central one, I determined to plant another orchard, and to give the trees of the first one away. The second orchard was planted of the finest varieties of apples recommended by Coxe, and all the trees obtained from New York, with the exception of some few kinds we had in the neighborhood. At this time I had a farm some few miles from me, on which there was an apple orchard that had been in bearing a few years. I determined to graft it with some of the finest varieties I had just got from the north. For that purpose, I had about half of the large limbs cut off a little ways from the body, near the first fork of limbs. The other limbs were left to keep the trees alive, that part of the limb left that was off, that had water sprouts, was then grafted. And those that had no sprouts were left to throw them out, to be grafted the ensuing spring; the other large limbs left were the ensuing spring cut off and grafted in like manner. The grafts that lived, had a split or piece of bark tied around to know them; and as they grew, the water sprouts were trimmed to give room. The grafts inserted bore a little the second year, and in five years they bore a good deal, and the tops of the trees looked large and fine. But some of the trees were very much injured by cutting the large limbs too near the body; decay extended from the cut through the limbs to the body. Limbs, in proportion to their size, should be cut farther from the body, large limbs several feet, and tar should be rubbed on the end of the limbs. It in a great degree prevents decay, but too much is an injury; it runs down on the bark in hot weather and scalds the bark. After the trees had come to bear a few years, I found most of the varieties did not suit this part of the country, and had to regraft nearly all my young orchard, one half of which was planted of the green Newtown pippin. This has long been considered the finest winter apple known. It bore well with me, but about the time of ripening nearly all would speck and rot on the tree. Some of the other kinds were no better. The following kinds I prefer; they have been bearing with me for many years; I will name them in the order they ripen. June-eating, Prince's harvest, a small yellow apple, summer pearmain, yellow bellflower, and Carthouse.

June-eating.—This is the earliest apple of our country: size small, form flat, color yellow, flavor pleasant, the skin of an oily feel.

Prince's harvest.—About two or three times as large as the June-eating, and something of the same form and color; fine to cook, but not good much in other respects.

A small yellow apple.—A seedling of this neighborhood, the size of a common crab apple; the form flat, flesh remarkably tender, rich and of delightful flavor, and an excellent fruit to cook. It bears only every other year, then abundantly; it ripens slowly. It is to be regretted that such an excellent apple should be so small, and to bear only every other year.

Summer pearmain. This is one of the very finest summer apples of our country; the size large, with us much larger than the cut in Coxe's Treatise on Fruit Trees. The color a reddish yellow, with streaks and spots of deep red; juicy until too ripe; the flesh very tender. It frequently cracks open on the tree and bursts from its own weight in falling. It is a fine apple to eat or to cook; it is free from rotting; ripens slowly

and lasts for a long time; it bears every year, but has its full and scanty years of bearing.

Yellow bellflower.—At a little distance from this apple, it has the appearance in size, form and color of the common quince of our country. It is an excellent apple to eat, or to cook; the flesh is rich, juicy and tender. It bears every year, and is one of the most productive apples of our country. The tree grows large and spreading, with pale leaves and hanging boughs. There is another apple, that should not be mistaken for this—the monstrous bellflower, a worthless apple, with fruit in appearance resembling the yellow bellflower. The difference in the growth of the trees is easily told; the monstrous bellflower has upright limbs, with very large foliage of a deep green. Some varieties of apples seem adapted to particular localities, whilst others seem to retain their excellence over a much greater extent of country: this appears to be the case with the yellow bellflower. It is represented by Coxe as "the most popular apple in the Philadelphia market;" and in the New American Gardener, published at Boston, a writer says, "This apple we can decidedly recommend from twenty years trial; it is a great bearer." But I do not think it as large here or as fine as I have seen it to the north; probably it would not do to cultivate much further south. This apple is considered a native of New Jersey.

Carthouse.—This I prefer as a winter apple to any other I have ever had under cultivation; it is an excellent apple, very productive, and bears every year. The following is Coxe's description of it: "This apple is said to have been brought from Virginia; it obtained its name from a family in the Delaware state. It is highly esteemed for its excellence as a table apple late in the spring, and as a good cider fruit. It is a most abundant bearer, and hangs on the tree very late in the season. The tree is hardy, of a handsome, open, spreading and vigorous growth. The fruit is small, the color a deep red, sometimes a little streaked with yellow; the skin of a polished smoothness; the form inclining to an oblong; the flesh is very firm, yellow, and rich, not fit for eating until mid-winter, when it becomes juicy, tender, and finely flavored." Coxe says this apple is small, but the cut he gives is over the common size with us; it may be said to be an apple of the common size, except when the trees are over full. The Carthouse, when gathered with us, are put in barrels or boxes in the cellar without any thing with them; in this way they keep until they are used. A cool dry cellar is the best place to keep apples, in fact they cannot well be kept any where else, without soon becoming dry and tough. I have read much that has been published on fruits, and I have taken much interest in this matter, and having frequently to pass from here to Mississippi, by the way of Baltimore, Cincinnati and Louisville, I have frequently gone to market, and to the fruit shops to examine the fruits, and from what I have seen, and trials I have made with many varieties, I have come to the conclusion, that were I to cultivate only three varieties of apples in this part of the country, I should cultivate the summer pearmain, yellow bellflower, and the Carthouse. These three varieties would give a succession of fine fruit from some time in August, until the ensuing spring, and would be more apt to bear annually than most other varieties. To persons wishing to cultivate a greater variety of apples than I have named, and who may be inexperienced in such matters, I would recommend the following varieties for trial: red June-eating, summer green, Roane's crab, wine apple, James river, black coal, and Gravestein. Red June-eating is said to be a fine early apple; with me it has not yet borne.

Summer queen.—This is represented by Coxe and others as very fine. I was under the impression, for some years, this variety was in my orchard, but it proved otherwise. I have since obtained a tree from the north for this variety, but as yet it has not borne. It is said to be a large apple, yellow color, with stripes and clouds of red, and "equally suited for eating and stewing."

Roane's crab.—Coxe states this apple to be a native of this state; that it originated on the farm of an individual whose name its bears. He says "it is an early and a great bearer every second year; the apple is small," "the form is round, the stalk thin, the skin yellow, with a small portion of russet about the stem, and spots of red scattered over it." "The liquor is remarkably strong, of a sirupy consistence when first made, but becoming singularly bright by proper fermentation and racking. It will keep perfectly sweet in casks well bunged, and placed in a cool cellar, through our summer months." I have frequently eaten this apple; it is only tolerable. Many years past I occasionally had a chance of drinking some of the cider; I thought it the best I had ever tasted. Persons wishing to raise cider of a superior quality should give this apple a trial.

Wine apple.—This is a very fine fall and winter fruit, and has succeeded in this neighborhood very well. The fruit is large, form flat, color red, streaked and spotted with small portions of yellow; the stalk end frequently of a russet color. The tree grows large, leaves small. This kind should not be mistaken for the winesap.

James river.—I know nothing of this variety; but I have seen it highly recommended as a winter apple.

Black coal.—A large red winter apple; this with me has not yet borne.

Gravestein.—A small winter apple. The two last varieties named, were introduced into this country a few years past, and are represented as very fine north of us; but experience must prove whether they are adapted to our part of the country.

Pears.—In early life I have purchased many varieties of pear trees, from the finest northern nurseries. I was then under the impression, it was like writing to a neighbor for a bushel of corn or wheat—what was written for would be received; but in this I was greatly mistaken. But for this, I could say much more on pears than I now can say. From what I have seen, and from what has been published, I should consider the following varieties the finest: green chisel, or Madeline, early Catherine and English Gargonelle, or summer bell. These are said to ripen before the peach. Seckle, a summer pear; yellow butter or St. Michael, a fall pear; Echasserie, a winter pear.

Green chisel, or *Madeline.*—I raised four trees of this variety, which bore with me for several years, but the blight which is so destructive to the pear trees of our country killed them all. This variety of the pear, I think, will not succeed well as far south as this.

Early Catharine.—I purchased a tree for this kind many years past, but when it came to bear it proved to be the green Catharine. I have since purchased another for the early Catharine, which has not yet borne with me. Coxe says, "this is more generally admired than any summer pear; it is remarkably fine, rich, waxy and luscious. Its form somewhat like a calabash, with a long curve neck, and a long fleshy stem; the skin is on one side yellow, the other a rich russet or brownish-red." Coxe's cut of this pear, exclusive of stem, is 2¼ inches in length, its greatest breadth 1⅜ of an inch, which is about ¾ inch from the blossom end.

English gargonelle, or *summer bell.* This variety has not borne with me as yet. Coxe says, "it is a tolerably large pear," "with a neck somewhat curved, and diminishing to a small point, with a long stalk, fleshy towards its junction with the fruit, the skin is a light green, with small cloudy spots, blended with russet, particularly near the stem, the cheek next to the sun has frequently a brownish-red color." Coxe's cut of this is about 2⅜ inches in length, its greatest breadth 1¾ of an inch, which is about one inch from the blossom end.

Seckle.—This is considered the finest pear known, and is supposed to have originated in the vicinity of Philadelphia, and is called after the name of the individual on whose farm it is supposed to have originated. Coxe says, "the form and appearance vary with aspect, age and cultivation, the size generally is small, the form regular, round at the blossom end, diminishing with a gentle swell towards the stem, which is rather short and thick; the skin is sometimes yellow, with a bright red cheek, and smooth, at other times a perfect russet, without any blush." "The tree is singularly vigorous and beautiful, of great regularity of growth and richness of foliage; very hardy, and possessing all the characteristics of a new variety." Cox's cut of this is about 2⅜ inches in length, its greatest breadth 2¼ inches, which is about an inch from the blossom end. I have two trees of this variety that have been in bearing for some years; they have been very healthy and productive, and not injured in the least by the blight. But with this pear there is a drawback that I have not seen noticed by any writer. About the time of ripening, storms beat down great numbers of them; they generally have broken stems; probably the limbs, which grow close and thick, are forced with too much violence against them; the stems may also be more brittle than usual. As they fall so they remain, never becoming any riper.

Yellow butter and St. Michael.—This is considered in excellence next to the Seckle, and a much larger pear, though Coxe has given cuts about the same size. However, this error may be considered corrected, as he calls it a large pear. This pear is said to be better when gathered before it is ripe and housed. I cannot say how this is, but I have eaten some very fine ones that storms had beaten down several weeks before the time of ripening, that had been housed. It is said to be "a never-failing and abundant bearer, and produces fruit at an early age. The tree is of small size." I had two trees of this kind, that bore with me for several years, but lost them both by the blight. I think it probable trimming caused their death. "From the great vigor and rapidity of the vegetation in America, pear trees, if much pruned, are apt to grow too fast. This appears to render them more liable to the effects of the fire blight than otherwise they would be."

Echasserie.—This pear has been extensively cultivated in our country for a great number of years, and is represented as an excellent pear, hardy, very productive, and bearing abundantly at a very early age; it is rather a small pear. Years past I purchased a tree, for this kind, but it proved otherwise. I have now some few trees grafted from a tree of this kind, owned by an acquaintance of mine, who is very much pleased with it. Mr. Prince says, Coxe erroneously calls it the ambrette. Coxe says the ambrette, "when ripe, is green; the skin rough with small russet spots, and some black clouds. Neither the crown nor stalk end is indented. The flesh is rich, juicy, and highly flavored." Coxe's cut of the ambrette is 2⅝ inches in length, its greatest breadth nearly 2¼ inches, which is near the middle. I have been more particular in the description of pears than I should otherwise have been, in consequence of their being very subject to the blight, for the pear-tree cannot be regrafted, like the apple, without running a great risk of losing the stock by the blight. I have planted out a good many quince stocks where they are to stand, and recently grafted the Catharine and Gargonelle to them, a little below the ground. Coxe says the pear "will take on the quince either by inoculation or ingrafting. The former mode performed above ground will produce dwarf trees; the latter mode, under ground, in the root, will in some varieties improve the pear; in all it will form a strong vigorous tree." The quince is much used for ingrafting summer tender pears, and for espaliers; they do not suit winter pears so well, as they are apt to crack." Another author says, the pear ingrafted on the quince "has the property of giving to the fruit it bears greater precocity, an increased size and improved flavor, but with this drawback, that the quantity is small, and product short-lived, as the age of the tree seldom exceeds ten or twelve years."

Peaches.—The first peach orchard I ever planted was made up of the finest varieties I could obtain in the neighborhood. The site was fixed on, and the holes dug, four feet deep and four feet wide, and filled up with two ox-loads of rich earth, mostly from the adjoining woods; the other earth used was rich earth from under some old peach trees. This earth was used after I left home in the morning, under the impression it was richer than the other. On my return home I found what had been done, and anticipated the result. I had read enough to know that the site of an old orchard was not a proper place for a new one of the same kind; and in this case I thought it would be much worse, as the earth was put in the very holes in which the trees were to stand. However, as I was not very partial to the site, I determined to plant the trees, and see the result. The trees were planted, and in a few days there came a heavy rain, and the earth in the holes sank very much, though it had been partially trodden. The trees sank so low, and were so much thrown out of a line, they had to be pulled up and replanted, and before the ensuing year a good many died, others looked sickly, and some were quite flourish-

ing. Wishing to have nothing more to do with this site, for an orchard, I had the trees pulled up, and thrown away, and determined to plant another of the finest varieties known in our country, at least as far as I could get information on the subject, to enable me to make the selection. I found it necessary to read the best treatises I could get on fruit trees; and in 1824, I ordered a good many varieties from a large nursery in New York, and in 1826, I ordered 100 trees of 17 varieties, mostly 7 trees of each variety, from a large nursery in New Jersey. With these I planted another orchard, and looked forward with pleasure to the result. But after it had borne a few years, I found it was more in want of an axe or a grubbing hoe than any thing else—there were so many unprofitable varieties: since which I have used the axe and hoe freely. Some of our largest and finest peaches are amongst the most unprofitable to cultivate. Within the last two years, I have brought under cultivation nearly all the first-rate peaches known in our books and catalogues, that I had not tried before, with a view of making out a fine and profitable succession, the season through. Of these varieties I cannot now say any thing, but of those varieties that I have long had under cultivation, I prefer the following:

Red Magdalen and *red rare-ripe* are very fine early peaches.

Oldmixon cling-stone (sometimes called red Catharine) is a large peach with a red cheek, and is one of the very finest peaches of our country, and one of the most productive. It ripens immediarely after the two just named. This variety is said to be cultivated in the vicinity of our large towns to the north, to supply the market. About two years ago, while in Baltimore, I had some conversation with a gentleman who owns a large nursery near town. He stated to me he had an acquaintance, who had supplied the Baltimore market with peaches on a large scale, for the last thirty years, and he told him he considered the Oldmixon cling-stone the most valuable peach he had.

Oldmixon free-stone.—A fine peach. It resembles the Oldmixon cling-stone in its external appearance, and ripens about the same time; but in other respects is not to equal it. I am rather inclined to think another peach can be substituted for this in a succession of peaches for this part of the country; however, as yet, I have been compelled to retain it.

Columbia, in catalogues of fruit trees called Columbia superb. A large free-stone peach of uncommon excellence. The skin yellow, covered with stripes of red, giving it a singular and handsome appearance. It begins to ripen about the time the Oldmixons are about half gone. This peach is too much disposed to rot about the time of ripening to be cultivated on a large scale, but, as yet, I have been compelled to retain it, but hope yet to get a more profitable one to supply its place. One tree of this kind, in a garden or yard, is desirable on account of its excellent and beautiful appearance.

Common Heath.—This, like the Oldmixon cling-stone, is one of the most valuable peaches of our country; the color white, and the form oblong. It ripens in the fall, and is considered the finest to dry, or to preserve in sugar or in brandy.

A few years past, I had 300 bundles of peach stones put up and distributed gratuitously through this and the adjoining counties. Each bundle contained twenty-five stones of the six varieties just described.

Grapes.—I have had about thirty varieties under cultivation, of the native and foreign varieties that have been most highly recommended by the best writers of our country on the vine. The five following varieties seem most generally recommended, notwithstanding they are objectionable in many respects, the last three of which I have only recently brought under cultivation—Isabella, Catawba, Herbemont's Georgia, Hyde's Eliza, and Lenoir.

Isabella.—The fruit is of a dark purple, of a large size, and oval form, with a pulp; supposed to be the most productive grape ever known in our country. It is supposed to be a native of South Carolina. I have had this variety in my garden for about twenty years, and for a number of years I was greatly pleased with it; but for some years this grape has been nearly destroyed by the mildew, throughout our country, with the exception of our large towns, and even in them it is said now to suffer much from the mildew.

Catawba.—This is a large grape, of a lilac or bluish color, covered with a beautiful bloom, which gives to it a bluish-purple appearance. The bunches are large and uncommonly beautiful. The foliage and berries resemble the red Bland (a native, erroneously called blue English) more than any variety that I have had under cultivation. As a table grape it is only tolerable; but is said to be one of our finest wine grapes. This variety I have had in my garden as long as I have had the Isabella. It is more subject to rot than formerly; but not as much so as the Isabella. It is supposed to be a native of Maryland.

Herbemont's Georgia.—The name of this variety has been recently changed by Mr. Prince, of New York, from Herbemont's Madeira, under the impression it is a native grape of Georgia, and is now so classed in his catalogue of native grapes. Mr. Herbemont and others who have written much in favor of this grape state it is rather too much subject to rot in wet seasons; but, notwithstanding, its cultivation is highly recommended, and it is now one of the most popular grapes of our country. Mr. Prince, in his Treatise on the Vine, says, "This is an excellent grape, either for the table or for wine; the latter has been sold in South Carolina, for two dollars per gallon before it was five months old. The vine is vigorous and an abundant bearer; it is remarkable on account of the young branches having white spots on them, as if a white pellicle had been partly peeled off." Mr. McCall of Georgia, one of the most successful cultivators of the vine in our country, represents the foliage of this variety of a light green color, the juice of the grape as white, the wine becoming of an amber color, of an exquisite nut flavor; the berries round, of moderate size, and nearly black, set pretty close on the bunches, and weighing about five ounces each.

Hyde's Eliza.—This variety I have been induced to give a trial from the recommendation of Mr. Prince, who thinks it one of our first native varieties. It was but little known when Mr. Prince published his Treatise on the Vine, but from it I will make an extract: "It is a flourishing vine, the fruit is of a medium size, blue when ripe, very

sweet, and has no hard pulp." He states it to be a native of New York of recent origin, that it came up in the garden of a Mr. Hyde, and that Mr. Hyde said he called it "the Eliza, because it was reared and nurtured by a beloved daughter."

Lenoir.—The vine is represented of vigorous growth; the fruit small and black, of a superior quality to ripen early and never to rot. It is not a great bearer; but notwithstanding it should be given a fair trial. It is highly recommended. It is supposed to have originated from the seed of a foreign variety in South Carolina, upon the farm of a person whose name it bears, and is classed with foreign grapes.

I have been as particular as I could, in giving a description of the fruits recommended, so as to enable the cultivator to know them. In conclusion, to save trouble, I will state, I keep no stock for sale of any kind; and as to fruit trees and vines I have none for sale, nor have I ever sold one. Yours, respectfully,

EDMUND F. NOEL.

Edmund Ruffin, esq.,
Cor. Sec. Board of Agriculture of Virginia.

EXTRACTS FROM THE ANNIVERSARY ORATION OF THE AGRICULTURAL SOCIETY OF SOUTH CAROLINA. BY GEN. JAMES H. HAMMOND.

* * * * *

The extraordinary progress of the growth of cotton has, it is well known, occasioned a series of calculations, at various periods, from the time of the invention of the saw-gin, to prove that it must soon shoot far ahead of the consumption, and that competition would in a short time confine its culture to a few favored spots. Contrary, however, to all reasonable expectation, consumption has advanced with the same wonderful pace as production; and relying on the frequent failure of past predictions, many are even yet sanguine that it will continue to do so for a long period to come. I very much fear that they are at last mistaken—that what has been prophecy for such a time, is shortly to be fact; and that the present depression of the cotton market is neither accidental nor temporary, but the result of natural causes, and likely to be permanent.

The rapid increase of consumption has been owing to causes which can be explained, and to which limits may be assigned. A spirit of improvement in machinery for manufacturing it had sprung up in England, some twenty years before cotton began to be cultivated in this country. The hand-frame, cylinder cards, woof and warp machine, spinning jenney, and power loom, followed each other in quick succession, and Watt soon taught the whole to move by steam. The quality of goods was in consequence very much improved, and prices also reduced, so as to recommend them at once to all classes of consumers. The raw material then furnished, as might be supposed, fell far short of the augmented demand, and production was in turn vastly stimulated. The supply increased from America with great rapidity after Whitney's gin came into general use, but new inventions in machinery continued, and as even the home market had not yet been overflowed, and the demand still kept ahead of it, until the general pacification of Europe and the world opened fresh markets to this new style of goods, which could never apparently be stocked. Peace, also, made money abundant. New and immense investments were made in manufactories, and cotton mills arose all over England. It was of no small consequence to the result that England was the seat of this great manufacturing revolution. Her incalculable wealth, her great naval, superiority, and her vast territorial possessions, scattered over every quarter of the globe, gave her the command of a commerce unknown before in the annals of the world. And during a period of profound peace, longer than mankind have enjoyed since the death of the elder Antonine—and happily not yet terminated—this great nation has devoted herself to almost the sole purpose of opening new markets and filling them with cotton goods. To all these circumstances is owing the rapid stride of consumption, which has thus far out-stripped all calculation. But these causes have run their cycle; their utmost effects have been fully felt; all the markets now accessible to cotton manufactures are kept not only stocked but glutted; and although peace should continue and improvements in machinery go on, and the power of England still remain unbroken, none of which, to say the least, are certain, it is impossible for consumption to increase in any thing like the ratio it has hitherto done.

That it will increase to some extent, in every given series of years, is perhaps certain. I believe that cotton goods must undoubtedly drive linen from the almost entire monopoly which it yet enjoys in the domestic uses of the continent; that they have, sooner or later, to clothe the naked barbarians of Africa, as well as the silk-robed myriads of the Chinese empire: to ascend the Euphrates; to break more effectually through the barriers of the Bosphorus, and penetrate to all the nations of the Black Sea, the Volga and the Obe; while every birth in a large portion of the old world, and in the remotest civilized corner of the new, creates a fresh demand. But all this must be the work of time. Popular prejudices must be broken down; the policy and the agriculture of nations now devoted to growing rival commodities must be revolutionized, and manufactures must spring up and gain the ascendency where poverty and ignorance and despotism now flourish. Years, perhaps centuries, must elapse before all this can be accomplished; and peace and commerce must, for all the time, hold the world subject to their benignant influence.

It might be thought that the great increase in the sales of raw cotton during the last year (1840) argues an equal increase of consumption. But it must be remembered that the sales of 1838 were nearly equal to those of the last: that this year they have again fallen off to a fearful degree, receding to a point below those of 1839, and not much in advance of those of 1837, and that in spite of the greatest falling off in the crop ever known in one year, there has been an actual increase of the surplus on hand in Liverpool and Havre. The large sales of the last year were in fact owing to the great fall of prices, and the reduced sales of this year, to the trifling increase of them in the early part of the season, thus showing, that in the present state of the markets,

the smallest advance instantly checks consumption, which would not be the case, if the supply had not, to say the least, fully reached the limits of the immediate demand. The disastrous condition of the manufacturers during the present year, proves also, that the purchases of the last, even by the trade, were speculative, and did not indicate the true ratio of consumption. Indeed it is now generally conceded, that ever since 1834, notwithstanding the great appearance of manufacturing prosperity, more goods have been turned off than were required for consumption, and have accumulated all over the world, to an extent not so easily perceived, but not less fatal in effect than the accumulation of the raw material in the great markets of England and France.

But while consumption is thus fluctuating—giving the clearest evidence that it has approached a point beyond which it cannot advance, except with the slow march of time and the mighty changes to which I have alluded, production is not only going forward with gigantic step, but yearly developing a capacity which proves that it has yet scarcely passed its infancy, and has been creeping lazily along, compared with what it can do. If we are to believe the English, the experiment of growing improved cotton in their Indian possessions, under the direction of Americans—from our seed, and prepared with our gins, is likely to succeed. Already has some of the new made cotton been sold in Liverpool at a price higher than that of our best New Orlean's brands. I do not, however, feel very deep apprehensions from this quarter. The sample sent was probably most of it from the little Isle of Bourbon, where the finest Sea Island cotton, next to our own, is known to grow. With a soil impoverished by 2000 years or more of cultivation; with a climate in which it rains continually for half the year, and for the remainder of it never rains, so that during one period cotton will not grow at all, and during the other must depend on dews and laborious irrigation; almost without animal power; with an idle and feeble race of laborers; paralyzed by absurd social forms; and subjected to the most unprofitable as well as the most wretched system of slavery; with all these drawbacks, I cannot believe that India will be able to compete with us. It is idle to talk of her doing so with other sections of our country. To Egypt—notwithstanding the temporary effect of the galvanic energies of Mehemet Ali—and to Western Asia, belong nearly all the disadvantages of India, without the benefit of English capital and English enterprise. Brazil and other parts of South America might become more formidable rivals, but their institutions are too unsettled, and their population too motley and uncivilized, if they had no other impediments, to give us serious alarm.

But the cotton growers of South Carolina need not look abroad for competition. It is much nearer home. It is our own kith and kin—the hardy and industrious and enterprising vanguard of civilization—that have levelled the gigantic forests of the south and southwest, and furrowed the rich bottoms through which pour the tributaries of the Gulf of Mexico, from the Suwanee to the Sabine, and that have but recently rescued from a slothful race the fertile empire stretching beyond the Sabine to the Rio Grande—who are destined at no distant day, to supply the foreign markets of the world with this inestimable staple. They have just overcome all the incipient difficulties of the enterprise, and are now prepared to put forth, on the finest soil and in the most favorable climate of the earth, an energy which must inevitably crush all serious competition.

A few facts will show their progress and our own. From 1789 to 1811, the production of cotton in the United States had increased from nothing to 90 millions of pounds, of which but 2 millions were grown in the gulf states, not counting Georgia and Tennessee among them. By 1826, these states had risen by slow degrees to 135 millions in a crop of 368. In 1834, the whole crop had increased to 457 millions, of which they produced 252 millions, or rather more than half. And in 1839, when the crop amounted to 830 millions, the same states grew 600 millions, having in the last five years doubled their production and made 100 millions more, while the rest of the cotton growing states in the aggregate had actually, for thirteen years previous, made no increase at all. The world is accustomed, especially of late, to speak with astonishment of the unparalleled progress of the growth of cotton in this country. Yet for fifteen years now the whole of that progress has been made in the gulf states. Notwithstanding the high prices, we have been stationary. Is not this a startling fact? It seems to me of itself to settle the question, and to leave no doubt that these states, having now but fairly prepared themselves for it, so soon as the check on consumption shall place in strict competition all the cotton growers of the world, and reduce prices to their lowest point, the cultivation of this staple must be confined almost entirely to these fertile regions.

Now, I believe, prices have already reached, if indeed they have not gone below, the lowest point at which we can profitably grow cotton in this state. The average amount of cotton made in South Carolina, and I may include a large part of Georgia also, does not exceed 1200 lbs. per hand. The average expenses per hand cannot be less than $35. When every thing is taken into account for which money is paid or labor abstracted from the field to make, I doubt whether the most judicious planter is able to reduce them lower. If, then, cotton sells at an average of 10 cents net, on the plantation, to do which it must bring in the seaports 11 or 12 according to the distance of transportation, the clear profits for each hand in these states will be $85. And this includes the rent of land. If cotton sells at 8 cents net, on the plantation, the clear profit, rent included, will be only $61. If this estimate be correct, it will be seen at once that cotton cannot be profitably grown here at 8 cents per lb. Yet this is at least as much as we shall realize for the present crop, and more, I believe, than we can safely anticipate hereafter.

If any one doubts the permanency or abundance of the future supply from other quarters at 8 cents per lb. or even less, let him look a moment at the profits of the planters in the gulf states to which I have alluded. The vast land speculations incident to new and fertile countries, and the fact that every thing has been conducted there on the credit system, have, it is true, involved those states in great embarrassment. But this does not affect the productive capacity of the soil. The average crop per hand there cannot be

rated at less than 2000 lbs. The expenses per hand I will estimate at $40, although when compelled to be economical, I see no reason why they should exceed our own. At 10 cents net, for his cotton, the gulf planter will make $160, clear, against $85 at the same prices here, and at 8 cents, $120 against $61; which shows that, at prices ruinous to us, he will realize a handsome interest on his investment. But while I have estimated our production fully as high as truth will permit, I am satisfied I have underrated that of some of these states, perhaps all. On their best lands 300 lbs. per hand is not at all an extraordinary crop, and more is often made. The planters themselves, though great advocates of short crops at certain seasons of the year, would scarcely be willing to estimate their average crops at less than 2500 lbs. At these rates of production, and even 6 cents a pound net, they will make the very fair profit of $110 to 140 per hand; and unless cotton is for ever to baffle all the laws of trade, it is certain that prices must ere long range about and possibly below that poin'.

A result so fatal to us could only be arrested by the want of sufficient land or labor in these fruitful countries. But of this there is no prospect. Both may be already found or soon placed there in ample abundance, to supply not only the whole quota furnished by the United States, but all that is now furnished by every cotton growing region, for the foreign markets of the world. A slight examination will show the fact conclusively. The crop of the world for 1839, the last of which I have seen a full return, and the largest perhaps ever grown, supplied the markets of the United States and Europe with a little less than 1000 millions of pounds. At the rate of 250 lbs. to the acre, it would require but 4 millions of acres to grow it all. The four states bordering on the gulf—Louisiana, Mississippi, Alabama and Florida—not to include that almost equally fertile section of Georgia between the Flint and Chattahoochie rivers—contain 130 millions of acres. If then only one acre can be found in 32 capable of producing 250 lbs. they alone can supply the present demand of all the foreign markets of the world, and of our own also. It is difficult to compute the entire crop of the whole world, including that portion which is consumed at home in other countries than our own, as well as that which goes abroad, but according to the most extravagant estimate which has been made—excepting however the very veracious returns of our late census takers—it cannot exceed 1500 millions of lbs. At the rate per acre mentioned, it would require but 6 millions of acres, or one in 21 of those contained in these states, to yield the whole amount, and supply the entire demand not only of the foreign markets, but of the whole human family at the present moment.

In this estimate I have said nothing of the magnificent wilderness which joins us on our south-western border. Texas alone contains 150 millions acres. The climate has not been fairly tested, and like that of other regions approaching the tropics, its vicissitudes may prove too great for complete success in the cultivation of cotton. As yet, however, those best acquainted with it regard it as the most favorable of all others, while a large proportion of its soil is undoubtedly as fertile as any which has ever yielded its fruits to the hand of man. Already it is swarming with the adventurous offspring of the great Anglo-Saxon family, and offering the most formidable competition to even the bountiful bottoms of the Mississippi and Red River. When sufficient labor shall have found its way thither, as it is now rapidly doing, no one can venture to assign a limit to either the extent or cheapness of its production of cotton. There is little question, however, that out of the 280 millions of acres, embraced in this country and our own gulf states, land enough will be found in considerable bodies of such quality as to grow, at 6 cents a pound, or less, cotton sufficient to supply the progressive demand of mankind in all time to come. For were they at this moment to be civilized by some supernatural influence, with every avenue of commerce thrown wide open, and every article competing with it drawn from the market to the full extent that probably they ever can be, the 800 millions who inhabit all the earth would scarcely require more; 8,000 millions of pounds. This they might produce on 30 millions of acres, or 1 acre in 9. And when it is remembered that one half of France and one third of England, barren as they were by nature, are now in actual tillage, it cannot be extravagant to suppose one ninth of these prolific soils well adapted to the growth of cotton.

Nor will there be any deficiency of laborers. White labor, it is true, can be made available only to a very limited extent. But there are in the United States and Texas upwards of two millions and a half of slaves, 1,500,000 of whom may be rated as efficient hands. Those who grow cotton make their own provisions, or can do it. To meet the remaining agricultural and domestic, as well as all other demands for slave labor, will scarcely require more than half these hands. So that the other half, or 750,000, may be employed in cotton culture. These, at even 2000 lbs. each, will produce 1500 millions of pounds, which is precisely the amount at which I have computed the crop of the whole world. But the present demand of all the foreign markets and our own can be supplied by 500,000 properly located; and there is little question that such a location will be speedily effected. This done, we shall have an actual surplus of slave labor on our hands.

If, then, the consumption of short staple cotton has reached such a point that the least advance on the present low prices immediately checks it, and one at which it seems scarcely possible, at any prices, to maintain it, if at the same time the production of this kind of cotton is increasing every where over the world, and especially in the countries bordering on the Gulf of Mexico, both in and out of the United States, who, though latest to begin its culture, possess such advantages of soil and climate as to have already far outrun all competition, and, having conquered most of the difficulties incident to new countries and new enterprises, do now furnish six-tenths of the demand of both the American and European markets, and are capable of supplying, almost immediately, the whole, at such prices as are utterly ruinous to us, if all these things be true, as I have endeavored to show they are, the conclusion is irresistible, that the planters of South Carolina will be speedily compelled almost if not altogether to abandon its longer cultivation."

* * * * *

"Deprived of cotton as our main crop, we shall be compelled to resort to every variety of production which our soil and climate affords, to make out a crop which may be profitably cultivated. Among them I have no doubt that cotton will always hold a place to some, though probably a small, extent. I have estimated the average production of the best cotton regions at 250 lbs. per acre. And although they have much that will do better, I think I may safely say, that land which will produce 300 lbs. need not fear any competition. We have no bodies of such land in our state. But here and there spots may be found, and by judicious management more can be made to do it. So that every planter who will be content to lessen materially his cotton crop, and commence at once to manure highly all he plants, may yet be enabled to grow some of his favorite article. For the bulk of his crop, however, he must adopt some of the substitutes I shall enumerate.

In all that I have heretofore said, I have spoken of short staple cotton exclusively. It is well known, however, that South Carolina is the largest producer of the best Sea Island cotton. In its finest qualities we have, I believe, as yet no rival. How far this crop may be profitably extended is uncertain. The consumption of it has fluctuated around the same point for the last thirty years, and we might infer had reached its maximum. But by a judicious system of culture, there is reason to believe that the inferior qualities—the Maines and Santees—may be grown so cheaply as to drive out of competition the Egyptian and better sorts of Brazilian which now rival them, and thus secure a larger market for ourselves. Our planters on the sea-coast already put in little enough to the hand, and are alive to the advantages of manuring. Let me recommend to their earnest consideration a much more extensive use of that implement which has wrought such a revolution in short staple culture within the last 10 years. I mean the plough. Horse power is in planting what machinery is in manufacturing. And it not only saves labor, but does better work and assists to preserve and renovate the land. Cato said—so long ago as his day—that "the best culture of land was good ploughing: the next best, ploughing in the ordinary way, and the next best"—but after these, "laying on manure." I commend his maxims to our Sea Island planters, and believe that by the adoption of them they will soon absorb a portion of the labor which will be thrown out of the short staple crop.

The culture of rice upon sea-board has stood the test of time and competition, and we may safely regard it as a great and valuable staple, of which no contingency is likely ever to deprive our state. The demand is steadily increasing, and offers a fair reward to those who will embark in its production. Although we grow three-fourths of the crop of the United States, only a small part of the state adapted to it has yet been prepared for cultivation. Vast inland swamps well suited for it, yet frown in barren gloom every where below the ridge, while many of our up country bottoms, which are destined at some future day to groan beneath its harvest, are now idle wastes, consigned to flags and rushes. The necessity which shall drive us to drain these grand reservoirs of disease and death, will one day be hailed as an inestimable blessing. We cannot too soon turn our attention to it, and instead of drawing our supplies of rice from the sea-board, we of the up-country may at no distant day send our tributes to unite with theirs in supplying the north, and western Europe, where this luxury is fast becoming a necessary of life."

* * * * *

"The innumerable streams which intersect the state, and the gradual fall towards the ocean of even the flattest parts of the low country, afford great advantages for draining, while nature has been extremely bountiful to us in materials for manure. In many parts of the state marl has been found in abundance, and at convenient points for water transportation: and no doubt it will yet be found where it is not thought of now. In other parts limestone exists to an unknown extent; and in others again salt-marsh and oyster-banks abound. Almost every where upon our rivers, creeks, and branches, and in our swamps, we have rich alluvial deposites, a portion of which may be well spared to recruit the exhausted soil near: and our forests furnish a boundless supply of leaves and straw, which in various ways may be converted into valuable compost. Possessed with these resources, and all the usual ones incident to farm yards, whenever we resolve to set seriously about it, I question whether it will be found near so tedious or expensive to reclaim our waste and renovate our worn out lands, as is now generally supposed. But this interesting topic alone would require all the time allotted to this occasion, and I must therefore pass from it to continue my enumeration of the substitutes to which we may resort when we can no longer depend upon our cotton crops.

"Although we now purchase from other states, probably one half the flour we consume, there is hardly any part of this state in which wheat may not be grown. Fair crops may now be occasionally seen within 40 miles of the sea-coast, perhaps nearer; and few soils or climates are better adapted to it than the upper parts of South Carolina. The flour made there, when skilfully managed, is not in the least inferior to the best that we receive from Virginia or the Lakes; and it only requires an impulse, such as the loss of the cotton crop will give, to convert our state into an exporter instead of importer of the article. The same may be said of every other kind of grain. We obtain large supplies of oats, rye, barley, and even Indian corn, from other states, when few or no states can grow them in greater abundance than our own. I do not allude to the fact to condemn the practice in the wholesale, as it is now becoming customary to do. The planter is but little more capable of raising to advantage every thing within himself than other persons, and if he is cultivating other valuable crops which will enable him on a fair calculation to purchase these things cheaper than we can now grow them, he is just as correct in doing so as the merchant is in buying his hat or the tailor his shoes, instead of making them in their own families. But when the more valuable crops fail, and the means of purchasing are taken from us, we shall be driven to produce provisions of all kinds, and I feel assured that we will soon find that we can do it as abundantly and cheaply as it can be done in any other place. The prospect of a foreign market is not very flattering, it is

true, but when England repeals her corn laws, which in a few years she will be forced to do, we can at least take our chances with the rest of the world for her market, and with some advantages on our side, if no unjust tariff shall prevent our receiving in payment such of her manufactures as we may not make at home.

But we might convert our surplus corn and grain into live stock as well as any people in the world, and thus keep at home immense sums which are annually drawn from us in exchange for horses, mules, cattle, hogs, sheep, and even poultry. Our climate has not been found too warm for any species of domestic animal. English cattle and sheep, as well as English horses, flourish even on our sea-board; and our mild winters enable us to keep all kinds of stock at comparatively little expense for either food or shelter. Our swamps are covered with natural and nutritious evergreens; most artificial grasses have been found to succeed; while among our own diversified productions, we have substitutes which render them scarcely necessary. Carrots, beets and turnips all do well. Pindars and sweet-potatoes, more valuable perhaps for stock than these, are peculiarly our products. With these two articles, the luxuriant cow-pea, and the common grains, we can, for 9 months in the year, furnish at a cheap rate, the richest and most abundant pasturage: and what country can do more? Indeed, in raising hogs, could we find a foreign market, or had we large cities or numerous factories among us to afford non-producing consumers, we could do a business not at all less profitable than growing cotton at 12 1-2 cents a pound. With tolerable pasturage, a hog weighing 200 lbs. net may be reared and fattened on 8 bushels of corn. On average land, 300 bushels to each hand and horse would not be more than a fair crop—100 bushels will feed the hand and horse, leaving 200 bushels surplus. With this 25 hogs, weighing 5000 lbs. net, may be raised. At 4 cents per lb. for this pork, or 6 cents when converted into bacon, the gross income per hand will be $200; while 1200 of cotton at 12 1-2 cents, will bring only $150 gross; thus enabling us to make a very liberal allowance for the trouble of attending to the stock and any errors there may be in the calculation. That we should, under these circumstances, ever purchase meat from other states, proves, I think, that there has been some want both of reflection and experiment. Yet, for this article, and other kinds of provisions, and for mules and horses, it is pretty certain that we send away annually in the aggregate the immense sum of $2,000,000 or more.

Tobacco and indigo our state produced largely at one time. They have been superseded by cotton, though still grown, I believe, in small quantities, and chiefly for domestic use. In some sections their culture can, and doubtless will, be revived with profit. The discoveries of marl and limestone will afford greater facilities for the manufacture of indigo than heretofore possessed. Sugar, of which we are now said to make 30 000 lbs. per annum, may be made here as cheaply, perhaps, as we can buy it, when the loss of cotton shall stop our supply of money from abroad. Unless, indeed, the duty be repealed, so that we can get it at half the present price, and probably in exchange for our provisions and other products. At all events its culture is practicable here; and where it will not granulate, an excellent and valuable syrup may be extracted from the cane; and that has been grown at 200 miles distance from the coast. Should it turn out that there is any ground for a statement which I have lately seen in a respectable agricultural journal, and apparently from a respectable source, that sugar has been made from corn stalks at the rate of 1000 lbs. to the acre, but a short period can elapse before every farmer in the country will regularly manufacture all he consumes.

Flax and hemp do well in the up-country. Castor and bene oil of the very best quality have been expressed in different parts of the state, and olive oil also may be made, for we know that the olive tree can be reared here. Tar, pitch and turpentine, considered so important elsewhere, we can produce to almost any extent; while with timber and lumber of several of the most valuable kinds, and with staves and shingles, we can for ages supply all the markets within reach, and do now furnish large quantities at excellent profits.

The cultivation of the vine has heretofore attracted some attention, but the attempt to make wine has generally been regarded as having failed. I have little doubt the failure has been owing in a great degree to the recent planting of our vineyards. It is well known in wine countries, that no vineyard is considered of much value until it has borne fruit for at least 20 years. Yet we have been disheartened because ours have not arrived at maturity in 5 or 6. A short and intense summer, or something in location equivalent to it, seems to be required for the perfection of the grape, and it is possible that being so far south, we may not be able to make the best qualities, at least of what are called white wines; though of this we should not despair until our mountain districts have been fairly tried. That we may, with due care and in due time, produce abundantly, in every section of the state, the light wines of Italy, and perhaps some of those of the south of France which are so highly prized, there is every reason to believe.

The experiments which have been made in silk culture leave no doubt whatever of our complete success in that. In fact, American silk is said, on very good authority, to be better than that made in any part of the old world. And in no part of America can it be better made than here. As a proof of this, an enterprising lady of one of our upper districts, obtained this year from the New York Institute, the first premium for the best silk grown and wove in the United States, against competition from almost every section of the union. It is stated by some of our historians, that so far back as 1759, 10,000 lbs. of raw silk was exported from South Carolina. Whether this be true or not, we all know that none of our soils are so poor, and no portion of our state so cold, as not to grow the mulberry in its utmost perfection. It is true that the enemies of the worm have been found very numerous, and its disease fatal; but it is ascertained that in all silk countries at least one half of them, from some cause or other, perish before spinning. If we were properly prepared to rear them, the mortality here would not, I am confident, be so great as that. And if, as it is supposed, nealy all that die fall victims of a disease called *muscardine*, and a remedy for that has

been discovered, as recently announced, in the use of lime, it is perfectly certain that in growing silk, we may very soon compete with, and probably excel, any other people. If by means of ice the worm can surely be retarded until the most critical periods of our other crops have passed, a crop of silk may be made which would be almost clear gain to the planter.

I have enumerated some of the most prominent of our productions to which we may resort when no longer able to grow to advantage the great staple, which for the last 40 years has absorbed all our husbandry. But why, when this event is made manifest, shall we confine ourselves strictly to agricultural pursuits, possessing, as we do, so many other resources, inviting and rewarding as amply here as elsewhere enterprise and industry? An all bountiful providence has blessed our favored region with mineral wealth of incalculable value. In many places within our state vast quantities of iron ore have long been known to exist, and within the last few years much enterprise has been exhibited and heavy expenses incurred to turn it to account. Already forges, furnaces, bloomeries and rolling mills, have been put in operation, and with every prospect of complete success. No coal has yet been found in the vicinity of any of these beds of ore. That is a discovery, however, which the geological character of the country gives ground to hope may be the reward of future research, while for a long time to come the immense forests near at hand will render it unnecessary. The consumption of iron of all kinds, exclusive of cutlery, in South Carolina, must, if she consume in equal proportion with the other states, exceed $2,000,000 per annum; and this sum kept among us would not only enrich the explorers of this hidden treasure, but contribute through a thousand channels to enrich the state. Veins of gold have also been opened, and some of our mines have proved more profitable, I am well informed, than any in the union—perhaps in the world. Quarries of marble, too, have been discovered, and beautiful specimens extracted: and granite forms the basis of one third of our state. Salt has been manufactured also on our sea coast, and there it no reason that it should not be made to any extent required.

GLEANINGS.

For the Farmers' Register.

King William county, May 18, 1842.

Peas may be successfully grown among corn, especially in light land, planted in every row, between every other hill, where the distance of the corn is 5½ by 3 feet; but much of the profit will be lost, if the old method of gathering by hand-picking be pursued. If planted before the 1st of June, after throwing the first furrow to the corn, the crop will have so nearly ripened by the middle of September, that the vines may be pulled up and hung on the stalks for a few days, when all the peas will be dried, (the few unripe ones dried green not injuring the sale.) Then they may be hauled to the barn-yard early in the morning, and after a few hours' sun, trod out with very little trouble. This method I have adopted from a neighbor, the profit of whose pea-crop for several successive years has exceeded his wheat. There were shipped from our county town, Aylett's, the past season, 10,000 bushels, at the average price of $1; and though my crop raised among the corn was but a very small part of this quantity, yet, at $1.12½ per bushel, I felt it, as a thrifty housewife with her good floor cloth of refuse rags, as so much "clear gain."

On the corn crop and its culture.—While I am satisfied by experiment that we have several kinds of yellow corn more productive on thin lands than the Maryland twin, I am not prepared to pronounce on the best for all lands. Our mode of culture I think about the best. After preparing the land well with plough and harrow on single beds, the grain is covered, and as soon as well up, with the single plough a list is thrown into the water furrow, leaving a space sufficient for a four-tooth cultivator, which leaves very little work for the hoe hands, except thinning the corn. We next throw a furrow on each side to the corn, lapping the dirt very moderately, and now the peas (small black-eyed) are planted; another furrow on each side over the whole field, and lastly the middles thrown out, which, on account of the list first thrown back, leaves a small water-furrow, and the land sufficiently level. A very slight weeding completes all necessary labor on that crop; for I have gleaned the fact that working corn, with almost any implement, after it tassels, is injurious rather than beneficial, while late working, in ordinary land, so effectually prevents the springing of grass, that there is nothing to be returned for the benefit of the succeeding small grain. Suggesting this idea to an observing farmer, who was in the practice of working his land too early and too late, a cold livery soil, readily *liquidizing* in winter, (excuse me for coining the word, which will, however, be very intelligible to the unfortunate owners of such lands,) he confirmed its correctness, by informing me that in a severe drought, fearing to break the roots on both sides of his corn, he passed his cultivators in a part of his field along every other row. The corn was no better than where they were not used; but in the succeeding spring, the wheat appeared a high bed and a low one, discoverable at a considerable distance. But I learned with surprise from my friend Braxton, not long since, that on Pamunkey it is a conceded point that wheat will not succeed after crab grass, which I believe almost invariably follows corn of the same year. We on Mattaponi have opposite experience.

Roots.—"The difference in the value of our roots fed raw or cooked" is so inconsiderable, except the Irish potato, or as a condiment for less savory food, that I doubt if the gain is equivalent to the cost of boiler, fuel and attendance. Grain is more digestible when cooked, but meal or fine hominy I think more valuable; for I have often observed whole grains of corn, although boiled, pass undigested even from ruminating animals.

Sassafras.—Being much annoyed at a former residence by sassafras bushes, I was informed by my old friend, the late Mr. Henry (Speaker) Robinson of Hanover, suffering with the like pest, that by leaving the original sassafras trees in clearing land, or turning out young ones in old land, the bushes would disappear. I accordingly had young trees trimmed and suffered to grow at

70 or 80 yards' distance apart. They have now acquired size to shade the cattle, but I have never seen a more abundant crop of the bushes than at present. I have tried grazing them at various seasons, deep summer grubbing, and cow-pens on spots without success; and believe there is but one infallible and permanent antidote, and this is what we in lower Virginia may well call the *grand restorative* of exhausted land, fire wood and rail timber, the old-field pine. On a farm adjoining me, as much infested with sassafras a few years since as perhaps any I ever saw, it is over a large surface entirely supplanted by the pine.

I will close these gleanings with a few observations on the subject of *gelding animals*. The operation should be done in warm weather, and exposure to wet or even damp atmosphere guarded against for a week at least. Without this precaution many a fine animal has fallen victim to tetanus or locked jaw. But the particular practice which I wish to suggest to my brother farmers is to substitute for the barbarous custom of searing, and the awkward one of clamping, the simple and safe one of tying the blood vessels, not with twine, however, but with animal ligatures, following the example of the surgeons: narrow strips of sheepskin dressed without tan, and rolled as the shoemakers do, will answer very well. The ends may be cut off short after tying, and in twenty-four hours all danger of bleeding will be over. Washing with salt water will be fully sufficient to excite suppuration, and anointing all the surrounding parts with elder leaves stewed in lard will prevent all inconvenience from flies. To all these items I would, as old Father Wesley, subscribe "Tried." W. G.

BENEFICIAL EFFECTS OF THE GREEN-SAND EARTH OF JAMES RIVER, RECENTLY OBSERVED.

By the Editor.

As it has fallen to my lot to make and to report much the greater number (indeed nearly all) of the experiments and applications of green-sand *alone*, as manure, in Virginia, and as the greater proportion of my applications have been profitless, or without effect, and the general results discouraging to the practice—notwithstanding some remarkable exceptions of powerful effects, produced by this earth—it is the more especially incumbent on me to report, without delay, some more recent trials and their very different results. The difference of results, with the supposed difference of circumstances, also, seems to throw some light, though feeble and uncertain as yet, on the heretofore dark and inexplicable differences of operation of what seemed to be precisely the same agent.

The new facts learned of the effects of the Pamunkey green-sand and green-sand marl, and reported in vol. 8 of the Farmers' Register, induced me to request of my son, who is co-proprietor and sole director of the Coggins Point farm, to resume the use of green-sand for experiment. His first experiment, stated below, was before reported (3d) p. 86, vol. x. Before its having any effect was despaired of, he saw at Evergreen the beneficial effects of an application, which he described in a communication published at page 645, vol. ix., and which experiment was commented on subsequently at page 135 of the current volume. This fact induced the larger application of last November. The green-sand earth used was dug from under the Coggins Point beach, which is all formed of it, after removing a few inches of sand, gravel or pebbles. The darkest was chosen, such being deemed the richest in green-sand. No gypsum was perceptible, nor any other known fertilizing ingredient, except the green-sand itself, and a few small fragments of shells, which would scarcely amount to as much as one per cent. of carbonate of lime in the whole mass.

Experiment 1.—In the spring of 1841, as much earth was dug, of the part first reached, as covered 8 acres, at 40 bushels to the acre. The land was a level loam, of good quality, then in wheat and clover. Two wide beds, in different parts of the ground, were left without being dressed, for comparison. The spreading carefully made to the marked outlines of these omitted spaces.

During all 1841, and up to 8th of May 1842, when the stock of cattle were first turned on, and soon grazed the whole bare, there had not been produced the least visible benefit or effect by the dressing. N. B. On this same land, the first observed very great benefits from green-sand were produced in 1827-9, and which did not remain but a few years, (See Exper. xxiii, p. 121, vol. ix., Farmers' Register.)

Exp. 2.—In December, 1842—Enough earth was dug (adjoining and precisely alike in appearance to the last) to cover 40 acres more, at same rate, (40 bushels,) on clover sown in the spring or winter previous. Of this, the first used, and taken from the top or most exposed part of the bed, as before, has shown no effect up to May 21st, when the clover had reached full growth, and mowing for hay had been proceeding some days. After the dressing had covered some 6 or 8 acres, a marked interval was omitted; and another one after 5 or 6 more acres had been covered. The dressed clover, on each side of the first of these omitted spaces, showed a very slight benefit in May, and at the second interval greater benefit; but not regularly, and not enough altogether to repay the expenses of the application.

Exp. 3. The same rate of dressing as above stated was continued, and though no more marked spaces were omitted to compare results, there could be no doubt of there being very great, though irregular effects produced on the last 10 or 15 acres dressed. This was most apparent at the broken lines, where the work had been interrupted; and as it had not been designed as the conclusion, the out-line of the spreading was very crooked and irregular. The difference in product was every where most marked, and the dressed clover a vigorous growth, of rich deep green color, while the clover immediately adjoining, and not dressed, was comparatively yellow and mean. Several small detached spots of luxuriant clover were seen outside of the general dressing, and surrounded by the mean growth; and upon looking for the cause of such superiority, in each case a lump of green-sand earth was found in the middle of the rank spot, which had been thrown beyond the general spreading.

If both these applications had not extended beyond 15 acres, the results would have indicated

that the manure was not worth any thing. In the next 10 acres, there was not enough benefit to invite more extended applications. And it required to see the last 10 of the 48 acres, to be sure that the effect was indeed very great, and profitable for the outlay, even if the direct benefit shall cease with this one crop of clover.

The inference drawn from the great difference of result, and which causes to be awakened renewed hopes of future success, is that the upper part of the earth, from being long exposed to air and water, has lost its fertilizing ingredient or power, and that by digging deeper to obtain the manure, as profitable effects may generally be produced on clover, if on marled or other suitable soils. The first digging, for so small a quantity wanted, was necessarily all shallow. And of the second, the first 10 or 12 acres were probably dressed with earth dug from mostly within a foot of the surface. The space dug was large enough to allow the carts to enter, and sloped outward for their easy ascent when loaded. Of course, the latter part of the work must have been generally from the deepest dug earth, though not regularly so. The deepest part was about 3½ or 4 feet in the green-sand earth. Other and more extensive applications will be made during this year, and some accurate experiments on a smaller scale, which will at least serve to show whether this new ground for hope be well founded, or as deceptious as others have before been found.

As little of the whole space dressed as really showed much and certain benefit from the application, and irregular and variable as were the actual effects, still there was enough benefit to furnish, in spots, some 12 or 14 acres of fine clover for mowing; some of it as rank and heavy as could well stand. And without the use of the green-sand, judging from the appearances on as good land not so dressed, there would have been very little, if any clover worth the mowing. Of this general fact, the occupant of the farm is convinced, though he was incredulous, and hopeless of any valuable result until very recently.

Coggins Point, May 21st, 1842.

THE GROWTH OF WIRE-GRASS KEPT DOWN BY TOP-DRESSINGS OF LEAVES.

When an interesting fact, observed on Coggins Point farm, seeming to show this effect, was communicated not long since to the Farmers' Register, the writer was not aware, and we had forgotten, that a still more obvious proof of the same effect had been before observed on the same farm, and noted, by Mr. A. Nicol, when he was the manager there. The passage of the journal of the farm in which Mr. Nicol wrote down the observation when made, by accident has again fallen under our notice. It will be copied below, in the precise words of his entry in the farm journal, as written September 2, 1838.

"There is one singular result attending the application of leaves as top-dressing to wheat during the past winter, worthy of notice. In scattering the leaves, they were extended over a portion of ground thickly set with wire-grass. There is now on the leaf-covered portion of ground a very scanty portion of this pest growing; while on the ground adjoining, the growth is very dense. The line of separation is very distinctly marked, and follows all the little departures from a straight line made in scattering the leaves. The cause of this singular and unexpected result is of course uncertain—whether caused by the smothering effects of the early application of the leaves, or something in them injurious to the growth of wire-grass, has yet to be ascertained. That the first should have caused such an effect is scarcely probable. The covering of leaves was much too thin [to smother the growth,] and the fact that the remaining portion of the patch [of wire-grass] has been since thickly covered with straw without producing such an effect, renders this supposition extremely improbable. Nor do I know of any quality possessed by pine leaves that should be unfavorable to the growth of wire-grass."

This is a very interesting fact, and one which admitted of being observed with great accuracy; and it is rendered the more valuable because of the like result since observed by another witness, to whom the fact observed was also both novel and inexplicable. Whatever may be the manner of operation, the good effect may be easily obtained by means very beneficial in other respects. It seems to us clear from the facts above stated, that it was not by smothering the wire-grass that its growth was obstructed—but truly by the other supposed cause, that is, some quality of the leaves poisonous to wire-grass; and that quality we believe to be the *acid products* of pine or other leaves. Wire-grass delights in calcareous earth in a remarkable degree; and therefore the antagonist principle, or food, which is acid, must be as much injurious.

By planting Irish potatoes on the worst wire-grass turfs, (with or even without ploughing,) and covering them over thickly with pine leaves, as has been recommended in previous parts of this work, perhaps it might be found an easy mode of raising a crop, and the cheapest mode for destroying the wire-grass sod, and converting it to manure.—Ed. F. R.

CHARCOAL AS A MANURE.

From the Transactions of the New York State Agricultural Society.

There is no subject connected with farming that requires so great attention as "*manure.*" Let the land be ever so sterile and barren, it has been fully ascertained that by a judicious course of manuring it can be enriched and made productive. Let the soil be as rich and as full of succulent matter calculated for the producing and

nourishing the variety of plants necessary to be grown for the use of man and the benefit of the animal creation, a continued course of tillage, and a series of years' neglect of manuring will certainly render it barren and unproductive. Upon the state of the soil on every farm depends the living, we may say, of the farmer and his family, and carrying out the principle in its most extensive sense, upon the activity and intelligence of the farming community depends the whole interest of the entire commercial and civil community of any country. These facts are so evident to any man, who will take but a moment for reflection upon them, that it is a wonder indeed that more attention has and is not directed to this all important question, as to what are the best manures? No doubt the manures that are well calculated to produce a decided and active influence at once upon many soils would not act so readily and so permanently upon many other soils; but there are many manures that so act upon all soils; or, at best, there are many applications that may be made to almost any soil, that if they are not manures themselves, form the basis upon which the principles of other active manures may be made to produce the most astonishing effects. I have recently had my attention directed to the use of *charcoal*, by the knowledge of some facts that have been communicated in answer to my inquiries, that have induced me to devote a paper to the subject, in the hope, at least, that it will excite attention, and be productive, in the end, of great good to the community by inducing a series of experiments upon the use of charcoal as a manure, that will result in immense benefit to the farming interest.

I shall not pretend to enter into a series of reasonings upon the chemical affinities of charcoal to the soil upon which it may be applied; these matters I shall leave to those whose education and pursuits have better fitted them to ascertain these things, by enabling them to reach them by chemical analysis, which I am unable to make. I shall simply state the facts which I have observed, and those which I have learned from others, whom I have requested to look to them, together with the results that have been obtained, leaving to others to say whether the question is not of sufficient importance to lead them to try whether the results will not be equally beneficial in very many other situations.

In the neighborhood in which I live there are a great many hearths of coal pits, as they are called; places where wood has been piled, and burned into charcoal, scattered about the country. I have invariably observed, that upon these hearths, in the course of a few years, a luxurious coat of grass made its appearance, when all around in the vicinity scarcely a blade of grass could be found, and what there was found out of the coal hearth was sickly and dwarfish. This was so well known that in the heat of summer, when the pasture in other places was dried and withered by the summer drought, it was a common practice to drive the cattle to the "coalings," as they are called, sure that they would there obtain food. During the last autumn, business called me into Harford county, in Maryland. While there I was surprised at the exceedingly luxuriant growth of a crop of grain but lately seeded in a field, on Deer creek, and also at the very peculiar appearance of the soil. The soil upon which the grain was growing had a remarkably dark appearance, and appeared to be so mellow and friable as nearly to bury the foot at every step, and although it lay very level, did not appear to the touch to be so; not as the soil in the other fields around it on the same level. My attention was excited by what I saw, and I inquired if the field had not been covered with charcoal, and was told that it had been. I inquired when it was done, and was told it had been spread upon it more than *twenty years* ago!! I then asked what was the general quality of the crops raised upon it, and I was told that they were invariably fine, both as to quantity and quality. The person who lived upon the property informed me that he had repeatedly hauled the soil from that field and spread it upon the surrounding fields, and he could, for years, or in fact from the time he spread it there to the present day, always see, by the growth upon these places, exactly where he had put it!!

I had for some time past had my attention directed to the subject, but here I found it fully developed to my full satisfaction.

When I returned home, I made it the subject of conversation frequently with the farmers in our neighborhood, and from one of them I learned that when he lived in Chester county, Pa., with his father, a part of their farm became worn out and unproductive. It was abandoned for several years, and in the mean time many coal pits had been formed upon several of the old fields, by drawing the wood there to burn into coal, that had been cut in the adjoining timber lands. After some time they again put those fields under tillage, and he states that wherever a coal hearth had been left, there the crop of grain and the growth of grass was equal, if not superior, to that which grew upon any of their most productive fields. Another case of the application of charcoal I have found in this neighborhood was made by a gentleman in the iron business to his meadow, near the coal house. He had a large quantity of the coal that had become too fine to be used in the furnace; he did not know exactly what to do with it, it was in the way, and he concluded, as the easiest way to dispose of it, to haul it out and spread it upon the grass land. He spread it late in the fall, and for many years he informed me he observed the most astonishing effect produced upon his yield of grass. The quantity was nearly double, and the effect continued as long as he owned the property, which was at least ten years; so he informs me.

From what I can see of its effects, where a large quantity is left upon the ground, as for instance, in the centre of the hearth, it takes a considerable time for it to acquire a sufficient degree of moisture to penetrate to the bottom, and until it has acquired that degree of moisture nothing will grow there. Around the outer edges of circles where it is thrown upon the ground it is soon saturated with moisture, and vegetation is soon facilitated, and goes on rapidly. I should judge, from this, that when about to be applied to land the coal should be ground fine, and then thoroughly wetted and sown or spread with a lime spreader over the surface of the soil. From the circumstance of its being easily powdered or mashed up, I should suppose that the process would be very easily effect-

ed by making a floor of plank, say circular, and procuring a good sized stone, to be affixed by a shaft to an upright post, throw the coal into the circular planked way, and attach a horse to the shaft passing through the stone, and drive him round, carrying the stone, in its passage, over the coals. A very simple and easy process, precisely similar to the old fashioned way of grinding or breaking up bark, practised by the tanners, previous to the invention of the cast iron mill now in use. The cost of covering an acre would be trifling, and if it produced no other effect than that of forming a permanent vegetable basis in the soil, for lime to act upon, it appears to me it would well repay a greater amount of labor and expense than would be necessary to try it.

I have just been made acquainted with another result of the application of charcoal to arable land, that if general, from its application, will induce its use by every one who can procure it at a reasonable price: that is, wherever charcoal has been applied *rust never affects the growing crop of wheat!!* My friend who has communicated this fact to me states, that he has observed it particularly, and when the field generally has been "struck with rust," as it is called, those places where he had applied the charcoal *invariably escaped.* J. H. Hepburn.

CAUSES OF FIRE.

Mr. J. Murray has published a letter in a Liverpool paper on the frequency, causes, and prevention of fire, which contains many facts well worthy of attentive consideration. Among other observations, he says—

"There is far too little attention paid to the locomotive engine on our railroads. The ignited coals that fall below are often blown to considerable distance, carried into the adjoining fields, and may, in contact with farming stock prove a serious evil; and I have witnessed brushwood and tufts of grass consumed by this means. A green taper, colored as it is by means of oxide of copper, when blown out, acts on an aphlogistic principle, and may continue to the end of the coil in an ignited though flameless state, and, in contact with combustible materials, may prove seriously destructive. It has set a mahogany table on fire—providentially discovered in time. Damp rags, *en masse*, may spontaneously take fire, and have consumed the premises. Linseed and other oils, but especially that of linseed, have been the fruitful sources of conflagration in cotton factories and the warehouses of merchants. Nets dipped in oil, and cast over the rafters in an outer shed, set them on fire; and a bale of cotton wool burst into a flame from linseed oil being poured upon it. Even animal matters, such as woollen, under such circumstances, come within the precincts of danger. I find that strong red fuming nitric acid will set fire to straw; and an accident of this kind once occurred to myself. The vapor of sulphuric ether, instead of being volatile, and ascending, as is generally supposed, falls to the ground like water; and accidents in the laboratory and shop of the druggist, from ignorance of this fact, are by no means unfrequent. I am personally acquainted with three distinct cases, wherein the premises were set on fire originating in this source. Specks of bull's eyes in window glass may, on the principle of burning lens, ignite inflammable substances brought within the limits of their focus; hence the curtains used in some factories may be easily ignited; thus, too, a water-bottle left in a window, may in sunshine be the means of setting premises on fire, especially in a house shut up during the absence of the family; and I have seen a silk curtain consumed to tinder by the concentrated rays of the sun, in passing through the show-bottle in the druggist's window. Spirits of turpentine will inflame if poured out in the hot sunbeam; and I am informed by the distillers of tar and turpentine that the head of the still cannot be safely removed for thirty hours after the fire has been extinguished, as an explosion might be otherwise anticipated. Lucifers, or Congreve matches are one of the fruitful sources of fires. Those that are called Dutch, containing phosphorus and having a very fœtid phosphoric smell, are exceedingly dangerous: they may ignite spontaneously at the temperature of summer heat; and it may now suffice to say that a recent conflagration has been traced to this cause. The cigar and the pipe are pre-eminent sources of modern conflagration; and I have no doubt that of the seat of the Marquis of Londonderry, and the late one of York Minster, are entirely attributable to the pipe or cigar used by the workmen engaged in repairs. It is not generally known that tobacco contains nitre, and that, like touchwood, it continues ignited for hours. Fires occuring from this cause are, I apprehend, too notorious to need specific detail. It is clear that the end of a cigar dropped among wood shavings might be fanned into a flame by a current of air; and tossed from the top of a coach into an adjoining field, and carried by the breeze into a farmer's stack-yard, hay ricks and wheat stacks may even burst into a flame. I believe many a cigar smoker is an unintentional incendiary.

"Fires in farm-yards also may originate from quick lime left in a cart under a shed, and moisture getting to it. Heat sufficient to cause combustion is developed. The spontaneous combustion of hay-ricks from the dampness of the hay, is a danger to which the negligent farmer is often exposed. In our present state of chemical knowledge it is idle to attempt to follow this phenomenon through its course, or to explain the reasons for the heat produced in fermentation. As water must be present in fermentation, it is probable that it is decomposed, and it is commonly said that the flame produced is the result of intense chemical action; but, as Dr. Thompson remarks, (System of Chem., vol. iv. p. 364)—'All the phenomena of fermentation lay for many years concealed in complete darkness, and no chemist was bold enough to hazard an attempt even to explain them. They were employed, however, and without hesitation too, in the explanation of other phenomena; as if giving to one process the name of another of which we are equally ignorant, could, in reality, add any thing to our knowledge.'"

IRON HOOPS FOR COTTON BALES.

From the South-Western Farmer.

Why so much opposition in New Orleans to this very valuable improvement in baling cotton, and why is it so?

The iron hoop possesses all the advantages of rope and many more; it is equally as cheap, as strong and as easily put around the bale, and has a great advantage over rope in the event of fire. You could not burn up a steamboat load, or a warehouse full of cotton bales, in a month iron hooped. A cotton bale never burns much, until the ropes burn in two, and the bale expands. Cotton iron hooped need not be insured down the river, nor in the city—nor need it be re-pressed in New Orleans. Many planters are now compressing their cotton to the shipping size, and in a little time it will be the general custom of the country.

Then, why shall the planters incur the great expense of a double cut at insurance—one down the river and another in the city, with a finishing touch of 75 cents per bale for compressing, when there should not exist the least necessity for such charges?

But the planters must expect the iron hoops to be violently opposed by the insurance and steam press interest in New Orleans; but they have only to persevere and act in concert to overcome all opposition.

It is said that the hoop where it presses on the bale, will rust and injure the baling cloth. Such an argument is not reasonable, as where the hoop presses on the bale is entirely water tight, and all of the rust must be on the outside of the hoop, which could be entirely prevented, by brushing the hoop with a little paint or pitch.

The hoop iron, is sold at the factories at 5 cents per lb. Now is the proper time for the planters to send on their orders for the growing crop; which can be forwarded through the merchants at Vicksburg or New Orleans—many of the factories in Pennsylvania, Ohio and Tennessee having agents in those cities. A. PLANTER.

FEEDING ON COTTON SEED.

From the South-Western Farmer.

Near Clinton, April 28th, 1842.

In your valuable number of the 8th inst., I read some suggestions from a correspondent and from yourselves, in relation to feeding on cotton seed; and as neither of you have mentioned the plan, upon which I think they can be most usefully prepared, I will give the result of my experience and my plan to the public.

I have a large kettle, which holds from 5 to 6 bushels, set upon a brick furnace, (which is less than one day's work for a mason to make.) I fill my kettle with cotton seed fresh from the gin, and then fill up the kettle with water, and boil something less than half an hour. Then empty the seed into troughs, and let my cattle and hogs to them. The milk and butter has none of that cotton-seed taste, which the green or uncooked seed give. Both cattle and hogs will keep in good order, winter and summer, on seed thus prepared; and when you are ready to fatten pork, you have only to add an equal quantity of cotton seed and corn, and boil as above. Experience has proved to me that it will fatten sooner, and be equally good as when fattened on corn alone. Your cows will give an abundance of milk all winter, when fed in this manner, with but one bushel of corn to four of cotton seed. Every one is aware of the advantage of boiling turnips, turnip greens and cabbage for the human stomach. The boiling of cotton seed is not less advantageous as food for stock. Besides, there is great economy in feeding seed thus prepared. By the usual method in feeding, there is more than double the quantity of seed wasted that are consumed by the stock.

So far as I have heard, every person who has ever tried this plan, has been well pleased with it. Very respectfully,

D. O. WILLIAMS.

Messrs. North & Jenkins.

THE FARMERS' REGISTER.

VOL. X. JUNE 30, 1842. No. 6.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

REPORT TO THE STATE BOARD OF AGRICULTURE,

ON THE MOST IMPORTANT RECENT IMPROVEMENTS OF AGRICULTURE IN LOWER VIRGINIA—AND THE MOST IMPORTANT DEFECTS YET REMAINING.

By Edmund Ruffin.

The time can yet be remembered by many persons now living, when the improvement of the general or average rate of product of land by its fertilization was scarcely attempted, or even thought of, in the lower and middle regions of Virginia. The efforts to increase the amount of the products and profits of agriculture, were not wanting then, more than now. But it was by adding to the cultivated surface by new clearings of wood-land, and by thus substituting fresh and richer ground for such as was worn-out and totally worthless. The manuring was almost limited to the partial saving and use of the excrement of the live-stock; no more vegetable matter, as litter, being used, or thought worth the labor of using, than would serve to absorb and retain the animal juices. Perhaps only the more ignorant cultivators believed that vegetable matter was not manure of itself; but of the more intelligent, but few would have deemed that the doubling the ordinary small amount of litter in their farm yards and stables, would not have been of more labor than profit, even for lands the best adapted to be benefited by such manures. With very few exceptions, there was no more litter used than necessary to prevent the cattle from suffering by the wetness and filth of their pens and beds; and to serve to soak up partially the fluid matter, of which otherwise the waste was manifest. The straw of the wheat and oat crops, and the stalks of the tobacco, were necessarily brought to the barns to be separated; and, with greater or less waste, these materials were in some manner necessarily converted to manure. But the much larger quantity of corn-stalks were left in the field, to be afterwards burnt out of the way of the next ensuing crop; and still less was any other supply of coarse litter sought or desired. Even this small extent of manure-making was a great improvement on the older practice. Thomas Adams, an observant and respectable old farmer of Prince George, who died about 20 years ago, told me that he remembered the first beginning, in that county, of keeping up the work horses at night, on litter, for the purpose of increasing the manure, instead of turning them out to graze in the pastures. The practice was introduced by a new overseer on Old Town farm, then one of the "quarters" of the head of the Carter family; and it attracted much more of notice for censure, than for applause or imitation. The comment of one of the neighbors was, that "whenever *he* should be obliged to make manure for his land, he should think it full time for him to move to the *back woods*,"—the name by which the more western settlements were then called.

With a few honorable exceptions, very few of the wealthy land holders, attended personally or regularly to the management of their farms, previous to the last 30 years. Still, some few excellent cultivators, and judicious managers of their farms, were profiting by pursuing a different course. Such were Philip Tabb of Gloucester, Fielding Lewis and John Minge of Charles City, and John Taylor of Caroline. The writings of the latter subsequently gave an impulse which may be considered as being the commencement of our improving state of agriculture, and with which the following recital will set out.

The 'Arator' of John Taylor, was published in a volume in 1813, and soon acquired a popularity, and a ready acceptance of its worst errors as well as its most valuable truths, which no other agricultural publication has obtained. The two most important improvements which the author thus made generally known, were both in regard to the using of vegetable matters as manure.

I. The making of farm-yard and stable manure, in which the vegetable materials are in very large proportion to the animal matter.

The first of these lessons, and great improvements on previous general opinion and practice, was the almost unheard of plan of using as litter all the vegetable offal of the crops, no matter how excessive the proportion might be to that of the animal excrement; or, in teaching a reliance on the fertilizing properties of vegetable matter as manure to soil, and food for plants, without regard to the amount of admixture of animal matter. And this, however universally understood now, so much, indeed, that the former state of general opinion can scarcely now be realized, was then totally new doctrine to nineteen in twenty of those who to it soon became converts. And the improved practice, thus brought about, was made the more extensive by another then novel lesson taught by Taylor, that the fermentation of manure before application was unnecessary and wasteful. Before that time, the little farm-yard manure which was made, was left exposed first on the yard, and next heaped, and in both states wasting, and the use lost, for a whole year before being used for the next crop of tobacco. The advantages and disadvantages of the different modes of preparing farm-yard and stable manure, of the different conditions when applied, will be again adverted to under a subsequent head, when the still newer practice of top-dressing on grass will be considered.

II. Manuring by "enclosing" or non-grazing, or excluding stock from fields when in grass, or not cultivated.

The next great improvement, and innovation on previous opinions and practice, was the plan of manuring fields by leaving on them, to die and decay, their own vegetable growth, whether of artificial grass, or, in its absence, of the weeds and other natural growth, whenever tillage crops

were not on the field. This, though it be Nature's own and universal mode of restoring fertility to impoverished lands, and therefore is offered to the observation of all persons, had not been practised before any where; nor had even the theoretical truth on which the practice rests, been received or considered. The plan may be claimed as an improvement entirely Virginian, in large and systematic use; and the first promulgation and extension of the practice was due to the mind and the labors of John Taylor, and especially to the publication of his 'Arator.' It is true, that this mode of fertilization is not suited to lands already in a productive state, nor where animal products are very profitable, or indispensable—nor where putrescent manures can be obtained by purchase, or from other foreign sources, more cheaply than to surrender the grazing of entire fields, however poor and bare of grass. But the system was, nevertheless, admirably suited to the general condition of eastern Virginia—nearly every farm of which presented much of exhausted, and miserably poor fields, producing, when grazed, very scanty sustenance to a half-starved stock of cattle, which, even if 100 in number on a particular farm, yielded very little return to the proprietor. One fourth of the number, if of well kept cattle, would have yielded more, in milk, meat, and labor, and nearly as much in manure. In fact, the gross product of the then large stocks of cattle on the farms of eastern Virginia, estimated at fair market prices, did not compensate their owners for the cost of keeping them, without including the enomous attendant expense of the fences dividing the several fields of each farm, and which were rendered necessary solely that nearly starved cattle might roam over the almost naked pasture fields. To adopt some other mode of keeping a much smaller stock, was of itself a great saving; and by so doing, all the natural growth of the fields, when resting from tillage, served to manure the ground on which it grew—giving back, in the large proportion formed from the air and water, perhaps twice as much of enriching matter as they had drawn from the soil. And however scanty might be the cover of weeds to the acre, the whole amount on the field would be greater than the owner could possibly have supplied to his farm in prepared vegetable manure; and moreover, it was already spread over the whole surface, and applied in the best manner, as well as produced without labor or cost. If the several fields of a farmer (under the then usual circumstances) were 100 acres each, and three in number, (the rotation, corn, wheat or oats, and rest,) while he could barely manure 10 acres of his corn field from the farm-yard and stable, and by naked summer cow-pens also, he could add thereto the slight but costless manuring of the 100 acres to which the rotation gave rest that year. Suppose this cover to the 100 acres to be worth but half as much as the other manure, (in the earliest practice, and the then most impoverished condition of the land,) the 100 acres so treated would at least receive the value of 5 other acres manured; and this would be adding at once 50 per cent. to the previous amount of manuring done, and that without any increased expense, or loss of other products.

But, great as was the improvement undoubtedly made by these two modes of vegetable manuring, there was much waste of effort, and much loss subsequently suffered, by applying improperly in practice the doctrines and instructions of Taylor, which were true in theory, and of which the application would have been profitable under other circumstances. It was necessary to learn, (what is now much better and generally understood, but what Taylor neither taught nor seemed to know,) that naturally poor land cannot be durably or profitably enriched by vegetable or putrescent manures, so as to be raised and kept above its original state of fertility. And on such lands, therefore, after a certain slight degree of improvement obtained, even the cheap manuring methods of Taylor were almost thrown away. And on better original soils, after being much recruited and enriched by such means, there are enormous and yearly increasing evils produced, in the troublesome weeds encouraged to grow, and the myriads of insects sustained by their growth, and which become depredators on the succeeding cultivated crop. Even the ploughing under the rank weeds on moderately rich land became a difficult operation; and, like the also difficult ploughing under of coarse unrotted manure from the farm-yard, was often very troublesome to tillage, and sometimes even injurious to the first tilled crop. But these objections do not lessen the merit of Taylor's "enclosing system," for a vast extent of impoverished fields, for the restoration and improvement of which, that system was not only profitable, but indispensable. The greatly increased and extended benefits of these and other applications of vegetable manures, were, however yet to be shown by the subsequent introduction of the knowledge and use of calcareous manures.

III. Marling, or manuring from beds of fossil shells.

This mode of fertilization, now so general through all the marl region of lower Virginia, was not practised except on three on four detached farms, and that to but small extent, before 1820. Some few and generally small experimental applications of marl had indeed been made, by different individuals, from 15 to as far back as 45 years before; but which applications, from total misconception of the true mode of action of calcareous manures, had been deemed failures; and without exception, of course, had been abandoned by the experimenters, as worthless; and the experiments had been almost forgotten, until again brought to notice, after the much later and fully successful introduction of the practice.

Henley Taylor and Archer Hankins, two plain and illiterate farmers, and near neighbors in James City county, were the earliest *successful* and continuing appliers of marl in Virginia. But at what time they began, and which of them was the first, I have not been able to learn, though visiting Mr. Hankins' farm for that purpose, as well as to see his marling, and making inquiries of him, personally, in 1833. Mr. Taylor had then been long dead, and his improvements said to be almost lost, by the exhausting cultivation of the then occupant of his land. Mr. Hankins was unable to say when he and his neighbor began to try marl. He was only certain that it was

before 1816. Yet, though these farms are within 12 or 15 miles of Williamsburg, to which place I had made visits once a year or oftener, yet I never heard an intimation of their having begun such practice, until some time after my own first trials in 1818. At that time, when led to the use, as I was, altogether by theoretical views, and by reasoning on the supposed constitution of the soil, as well as the known constitution of the manure, it would have been to me the most acceptable and beneficial information to have heard that any other person in Virginia had already proved practically the value of marling. The slow progress of the knowledge of the mere fact of marl having been successfully used before that time, was a strong illustration of the then almost total want of communication among farmers, as well as of their general apathy and ignorance, in regard to the means of improving their lands.*

Much earlier than the commencement of marling in James City, the practice had been commenced, (in 1805) in Talbot county, Md., by Mr. Singleton. His account of his practice is in the 4th volume of the 'Memoirs of the Philadelphia Agricultural Society,' dated December 31, 1817, and first published some time in 1818. But successful as was his practice, and also that of Mr. Taylor and Mr. Hankins in connexion with much worse farming, it is certain that neither of these individuals had the least idea of the true action of marl; and they were indebted to their good fortune, more than to any exercise of reasoning, that they received profitable returns, and did no injury by marling. They all three applied their putrescent manures with the marl. But though this was the safest and most beneficial plan, the thus uniting them prevented the separate action and value of putrescent and calcareous manures being known, compared, and duly appreciated.†

My own application of marl, on Coggins Point farm, Prince George county, which in 1818 extended only to 15 acres, (of which but 3 or 4 were under the crop of that year,) by 1821 had been increased to above 80 acres a year, and so continued until nearly all the then arable land on that farm requiring it, (more than 600 acres,) had been covered. In 1821, my earliest publication on the subject was made. Though the facts and reasoning thus made known by that time were beginning to attract much notice, and to induce many persons to begin to marl, still it was some years later before incredulity and ridicule had generally given place to full confidence in the value of the improvement. Even at this time, when nearly 25 years of my own experience of marling and its benefits have passed, and the results are open to public notice and scrutiny, not half the persons who could marl are engaged at it, or are marling to but little purpose; and of all who are using marl, nineteen in twenty are proceeding injudiciously, without regard to the mode of operation of the manure, and therefore are either doing harm, or losing profit, almost as often, though in less degree, as doing good. At this time, however, there are scarcely any persons, however negligent in practice, who do not fully admit the great value and certain profit of applying marl whenever it is found.

But with all the existing neglect of using this means of fertilization, and with all the still worse ignorance of or inattention to its manner of operating, there never has been a new improvement in agriculture more rapidly extended, or with such beneficial and profitable results. In Prince George county, there is not one farmer having marl on or near his land, who has not applied it to greater or less extent, and always with more or less profit—and, in most cases, largely as well as profitably. In James City county there has been perhaps the next largest as well as the oldest practice. In York county, as in James City, some of the most valuable and profitable improvements by marling have been made. And some of the farms of both counties, adjoining Williamsburg, and having the benefit of putrescent town manures, show more strikingly than any others known, the remarkable power of calcareous manure to fix the putrescent in the soil, and make them more efficient and far more durable. In Surry, Isle of Wight, Nansemond, Charles City, New Kent, Hanover, King William, King and Queen, Gloucester, and Middlesex, counties in the middle of the marl region of Virginia, marl has been already extensively applied, and the profits therefrom are annually increasing. And in other surrounding counties, worse supplied with marl, the practice has been carried on in proportion to the facilities, and to the more scanty experience and degree of information on the subject. It would be a most important statistical fact, if it could be ascertained how much land in Virginia has already been marled. The quantity however is very great; and all the land marled has been thereby increased in *net* product, on the general average, fully 8 bushels of corn or oats, or 4 bushels of wheat—and the land increased in intrinsic value fully 200 per cent. on its previous value or market price. Where the marling has been judiciously conducted, these rates of increase have been more than doubled. From these data, might be calculated something like the already prodigiously increased values and products due solely to marling, and which will be still more increasing from year to year. If not already reached, the result *will* soon be reached, of new value to the amount of millions of dollars having been thus created. It is not designed in this hasty sketch to enter into minute details of results, nor to prescribe rules for practice, both of which have been given in other publications. The purpose here is but to state improvements and describe results in general.

It required the improvement by marling, on originally poor or middling soils, (or liming, which in final and general results is the same thing,) to render as generally available the best and otherwise but rarely found benefits, of the two kinds of vegetable manuring recommended by Taylor. When such soils have been made calcareous, by marling or liming, then, and not until then, all the benefits, present and future, that his readers might have been induced to ex-

* See more full account at page 108, vol. i. Farmers' Register.

† See Mr. Singleton's letter, p. 228, vol. iv. Philadelphia Memoirs, and republished, with preliminary comments, p. 89, 2d Ed. of 'Essay on Calcareous Manures'. Also notices of other earlier experiments at same page, and in note at page 36.

pect, may be confidently counted upon. In my own earlier practice—and Taylor had no greater admirer, or more implicit follower—I found my farm-yard manurings on acid soils scarcely to pay the expense of application, and to leave no trace of the effect after a very short time. And land allowed to receive for its support all its vegetable growth (of weeds and natural grass) of two and a half years in every four, and the products in corn having been measured and compared, showed no certain increase in more than twenty years of such mild treatment. Since, on the same fields, farm-yard manures, in every mode of preparation and application, always tell well, both in early effect and in duration. And even the leaves raked up on wood-land, spread immediately and without any preparation, as top-dressing on clover, always produce most manifest improvement, and are believed to give more *net* profit than any application of the much richer farm yard manure, per acre, made on like land before it was marled. This utilizing and fixing of other manures, and the fitting land to produce clover, which effects of marling are in addition to all the *direct* benefit produced, would alone serve to give a new face to the agriculture of the country. Whatever may be done by clover, and almost every thing that can be done to profit by vegetable manures, on the much larger proportion of the lands of lower Virginia, will be due to the application of marl or lime.

IV. Liming.

The kindred improvement by liming began to be extensively practised on some of the best James river lands, where no marl was found, soon after the use of the latter began to extend. Who may have made the earliest and small applications of lime is not known, nor is it at all important. The earlier profitable use of lime in Pennsylvania, and the much earlier and more extended use in Britain, were known to every well-informed or reading farmer. Such a one was Fielding Lewis of Charles City, as well as a most attentive, judicious, and successful practical cultivator and improver. He is believed to have been the earliest considerable limer, and the one who obtained the most manifest profits therefrom, and whose example had most effect in spreading the practice. Some of his disciples and followers have since, in greater rapidity and wider extent of operations, far surpassed their teacher and leader—to whom, however, they award the highest meed of praise for bringing into use, and establishing this great benefit to the agriculture of lower Virginia. Nearly all the best soils on James river are comparatively of low level, as if of ancient alluvial formation, and have no marl with which the neighboring higher and poorer lands are mostly supplied. Of such rich lands, are the farms of Weyanoke, Sandy Point, Westover, and Shirley, &c., in Charles City, and Brandon (Upper and Lower,) in Prince George—and on all these lands, as well as some other, lime has been largely applied. The use is extending to the lands on all the tide waters of the state; and it has recently received a new impulse from the low price at which northern stone-lime is now brought and sold. It is ready slaked, and the vessels are loaded in bulk. The lime is sold on James river at 10 cents the bushel, and even may be contracted for at 8 cents, from vessels that come for cargoes of wood, and would come empty but for bringing lime. The greater lightness and cheaper transportation of lime, will enable it to be applied where marl could not be carried with profit; and with the two, there will be but little of lower Virginia which may not be profitably improved by calcareous manures.

V. Introduction of clover, and its application directly as manure.

As has been already observed, incidentally, the clover culture of Virginia is due to the previous use of calcareous manures. Without enough of lime, or some combination of lime, to constitute a really good soil, and still more on sandy lands, as most are in lower Virginia, it is almost impossible to raise clover at all, and always unprofitable to attempt it in field culture, and as part of a regular rotation. It is true, that on some of the best and richest natural soils, such as were just above named, and on the repeatedly and long manured house lots of worse original soils, some good clover had been made. But even there, the products were precarious. Field culture of clover was out of all question, and failed wherever attempted in lower Virginia, except on the best and very peculiar natural soils. It may even be doubted whether it was any where so productive, and so certain, as to be a profitable and regular manuring crop of the rotation. But after marling or liming, clover grew much better on the few places on which only it could be raised at all before, and it also became a crop as sure as any other, and *naturalized* as it were, on the before foreign and altogether unsuitable soils. It is true that marl or lime, alone, will not produce heavy crops of clover on very light or other very poor land. But even there, a good and healthy "stand" of clover is readily obtained, the plants taking and keeping possession of the ground, and are fit to be raised to a heavy crop by other auxiliary means—such as putrescent manures, and also gypsum, and perhaps green-sand. For according to the present feeble and uncertain lights on both the latter substances, the balance of testimony, furnished by my own experience and the operations of other persons in lower Virginia, is in favor of their acting well as manures on clover generally on naturally calcareous or marled and limed land, as well as of their having no useful effect an acid soils.

Clover is a most valuable addition to the comforts and minor profits of a farm, and also as an indirect fertilizer, by increasing the supply of animal manure. But its great benefit is different from, and superior to all these—and is to be secured by the crop being turned into the soil, and thus serving directly as manure for the crop of wheat to be sown thereupon. This process of culture, and mode of manuring, though not original in lower Virginia, but derived from the upper country, is believed to be peculiar to the United States. For though it be called by the same name, (fallow,) as is the best preparation for wheat in Britain, the two processes, and their designed and actual effects, are altogether different. In Britain, the object is to cleanse a field which had become foul with the grass and weeds which had been encouraged to grow and take possession of the land, by the moist climate, and

the want of enough hoed crops (like our Indian corn,) in the British rotations. And the object is effected by repeated ploughings and cross ploughings, harrowings, raking and hand-picking of root weeds, continued at intervals through a whole year, during which the land is kept as naked as possible. On the contrary, in the perfection of what is so improperly called "fallow" for wheat in Virginia, a heavy growth of clover is raised, and the second crop, if not also the first, (as is the practice of some of the best farmers on James river,) is left ungrazed and unmown, to be well turned under in August or September, by good ploughs drawn by 3 or 4 horses; then to harrow the new surface, and close the seams between the furrow slices; and without more stirring of the earth, (if possible,) to sow wheat thereupon, at the proper time, and cover the seed with harrows if soft, or such other shallow cutting implement, as the degree of hardness of the surface may require. The object is to have but one, and that a good ploughing; (unless the quantity of wire-grass or blue-grass compel a subsequent shallow ploughing;) and this restriction to one ploughing is not only to save labor, but to secure the clover manure below, and out of the way, and to keep a clean surface above, of which the tilth and mellowness are maintained by the gradual yielding and sinking of the mass of clover turned under. Such a coat of clover is an excellent manuring for the wheat succeeding, and moreover has been obtained at small cost, as its broad leaves drew its principal nourishment from the atmosphere. The smothering growth, also, of thickly set and rank clover, serves to keep the land clean of almost every thing but the clover itself, which is ploughed under deep enough to be effectually put out of the way of the succeeding wheat. The total and sudden change, also, of the condition of the field, by the ploughing and complete burying of the clover, and the leaving for some time a perfectly bare surface, must serve to starve and destroy nearly all the depredating insects that fed on the clover, and which, if not thus destroyed would continue to feed on the wheat. Thus *wheat on clover*, if well managed in all respects, is an admirably clean crop, both from weeds and from insects, and is heavily manured by the clover, which experience has proved is well adapted as a manure for wheat. Hence, it is not strange that the very best crops of wheat that can be obtained from the land, are raised by this mode of manuring with clover.

In speaking above of the practice of ploughing in clover to precede wheat, as being peculiarly American, it was only meant in reference to it as in regular and profitable use, and forming a part of the ordinary system of rotation and culture on some farms. The like explanation and understanding should be applied to several other things spoken of in this piece, as new improvements here. It is certain that the ploughing under of various green crops, as manure, and especially clover, has been sometimes done in Britain in modern times, and still more formerly in Greece and Italy, judging from the recommendations of the practice by ancient writers. "But," says Sir John Sinclair, "notwithstanding the recommendations of the ancients—notwithstanding the great need of manure—and the excessive price of every extraneous article of that description—this practice is now in a great measure abandoned. Peas, buck-wheat, clover, and other juicy plants, when ploughed in, yield no doubt a portion of manure; but they do little more than *restore* the nourishment they had abstracted from the soil; whilst it is extremely difficult to plough down rank vegetables in a growing state, so as to cover them in a complete manner. The farmers of Scotland are, therefore, of opinion that the only way of securing the highest degree of benefit from green crops, is to cut and bring them into a state of putrefaction, before they be applied to the soil." (General Report, &c., of Scotland, vol. ii. p. 530.) That, in the very different circumstances of Britain, the ploughing in of green clover may be bad economy, may be admitted, without affecting the propriety of the practice in Virginia. The like admission may apply to sundry other processes which are proper and economical and preferable here, and which would be the reverse in Britain, in Flanders, and still more in China. But the distinguished and able agriculturist above quoted was altogether wrong in his main theoretical ground of objection, viz.: that crops ploughed under only *restore* to the soil as much as they had previously abstracted. He forgot, or was not aware of the much larger portion of their substance which most plants, and especially clover and other broad-leaved plants, draw from the atmosphere and form into substantial vegetable matter, from the elements of air and water. But for this, the most bountiful provision of nature for the productive power of the soil, the draught therefrom on every farm, would regularly exceed the returns by manuring, &c., by the whole amount of crop sold off; and certain and rapid exhaustion, would necessarily be the consequence, to every part of the cultivated face of the earth, not regularly and abundantly supplied with putrescent manures from abroad. Yet all know that but a small proportion of the products of a field being returned as manure, will serve to maintain, and under favorable condition of soil, &c., may even greatly increase its productive power.

Perhaps there is no improving process or general practice, of one country or district, and however peculiar to it, that has not been used in some, and it may be many, isolated cases elsewhere. But, the very fact of such trials, however numerous, being rare and remaining separate, and not becoming general practice even on a few farms, is enough to prove that the processes or plans were not found profitable—and that such practical operations were but exceptions to the general rules of approved procedure. If there is any one of the modes of enriching by putrescent matters here spoken of, which might be supposed altogether new, it would be the plan introduced by Taylor, of manuring land by its own vegetable cover, wholly or in part, left to decay on the fields. Yet even this was advocated in Scotland, by Lord Belhaven, in 1707, and his publication is quoted by Sinclair, for the purpose of strongly condemning the opinion. The passage from Lord Belhaven is as follows: "I must say, by-the-by, that if in East Lothian they did not leave a higher stubble [when reaping grain,] than in other places of the

kingdom, they would be in worse condition than they are, though bad enough. A good crop of corn makes a good stubble; and a good stubble is the equallest enriching that can be given." (The Country Man's Rudiments, p. 23.) On which Sinclair remarks, "Such sentiments are now condemned by the practical farmer, whose object it is to cut and to bring home the whole, or nearly the whole straw; under an impression that, *unless it be brought into a putrefied state in the fold yard, little advantage, as a manure, can be obtained from it.*' (General Report, &c., of Scotland, vol. ii. p. 510.)

VI. Top-dressing with putrescent manures, and especially on clover.

After allowing all merit due to the improvement to be made by collecting, and to the greatest possible extent, more vegetable materials for farm-yard and stable manure—and also for the greater benefit of applying such manures on lands marled or limed, there would still remain a powerful obstacle to the extension of manuring, in the enormous amount of labor required, on Taylor's proposed plan, to carry out the manure in the spring, and plough under for corn before planting—to say nothing of the difficulty of tillage, and of danger to the young plants in dry weather, by the presence of 50 large ox cart loads (4 oxen for each,) per acre, the quantity of which he speaks. In so short a time, and in a busy part of the year, it is impossible, with the ordinary force of the farm, to carry out, spread, and turn under in proper manner, all the manure that could be made from all the offal of a grain farm—independent of the leaves and other materials which ought to be used. If, to lessen these difficulties, the manure be earlier heaped and fermented, then indeed it is made more manageable and more speedily operative; and the time for applying it is extended. But, on the other hand, the *whole* labor is increased, and the manure loses much of its fertilizing principles by fermentation. A third choice remains, which is to leave in the farm-yard, without heaping, and undisturbed, either all the manure, or all that cannot be conveniently carried out before planting the corn land intended to be so manured. The balance, or the whole so left, rots slowly through the summer, and may be carried out in September on the clover land, to be ploughed immediately for wheat; or otherwise kept until the next spring, to be ploughed under for the corn crop. In the first case, there is lost the use of the manure for six months, and in the second for a whole year; and in both, during the delay, the manure must lose much of the gaseous products of decomposition, which there is nothing growing to receive and secure. I have tried and suffered loss by all these three courses; and was fully sensible that in all, either the waste of manure, or the loss of its use by delay was very considerable.

The plan of top-dressing is an admirable means of overcoming most of these difficulties—and indeed all the important difficulties, if there be no *greater* waste of the fertilizing principles of manure spread on the surface of the soil, and no less benefit to the growing crop, than if the manure had been buried by the plough. Both these points are disputed, and there have been no careful or conclusive experiments made to decide the question. But from my general experience and observation, and now general practice for 12 years, I am satisfied that the evil of the greater waste of manure or of its effects, if indeed there be any greater, is not to be compared to the great saving of expense, found in applying the manure as top-dressing on clover, in March and April, or even somewhat later. When thus applied, and spread evenly and immediately, as it should be, the first rain carries into the earth all the soluble and active parts, and they are absorbed immediately by the roots of the clover, the growth of which will show the benefit in a few days. The coarse parts of the manure, are soon covered over and kept shaded and moist, by the growth of the clover, and thereby the rotting is both hastened, the products preserved better from waste; and every rain carries to the roots, and puts them to immediate use, as food for the growing plants. Thus, a good growth of clover is made even on inferior land, and perhaps by food that might have mostly gone to waste, if the manure had been fermented and made hot in the heap—or more slowly, by lying spread during all summer over the cattle yard. And this clover manure, being more than half derived from the atmosphere, would be worth to the succeeding crop of wheat or corn, more than double the prepared manure it fed upon and consumed. The saving of labor also is great. The mode of application permits the manure to be carried out in any state, from the time of the earliest beginning of the spring's growth of clover, to the first of May; and, if not before so used, even if put out at any time in summer, would do as well, except that the benefit of helping the earlier growth would have been missed. But as to summer-made stable manure, which is so generally injured by fire-fanging, if bulked, or wasted, if spread open in the stable yard, it is decidedly better to spread it on clover, during all summer.

The best application of top-dressing is to clover, because every portion of the manure so used by the clover, is converted to (probably) double the value of the manure in clover, ready to be again used by the wheat the same year. But though clover, as a broad-leaved leguminous plant, (or of the pea tribe,) draws more of its nourishment from the atmosphere, and gives more of manure to the next crop, than any other grass, still, if clover were not at hand, the top-dressing should be given to any grass or any weeds that stood thick enough soon to cover and shade the manure, and to increase the growth of which would be beneficial to the land, and to the succeeding crops.

But there is another material for top-dressing to which there can be no objection on the score of supposed waste, or because any thing better or more economical could be done with it, and which application is highly beneficial. This is leaves raked up in wood-land, and laid on young clover, in winter or spring. Valuable as is this material, on account of its abundant quantity, and usual cheapness of supply, it is very poor in quality compared to straw; and would perhaps not be worth the labor of double hauling and twice handling, required to carry it through the farm-yard to prepare it for manure. And dry or unrotted leaves would be very troublesome to plough under, and if thick might do more harm than good.

But when spread on clover, not too thickly, immediately from the woods, there is little trouble, no possibility of injury, and a decided improvement to the clover, and of course to the next wheat crop, and to the land. Wheat straw, spread in July, or later, on the young clover sown the year before, is also a valuable manure; and may be applied most advantageously on the poorest spots, by bringing back to the field return loads of straw, when carting the wheat from the field to the thrashing machine.

Another, and perhaps the best mode of dressing by pine leaves, (which are best, because they will not be blown away by high winds,) is on wheat, as soon as possible after it is sown. This is too busy a time for much of such manuring to be then done. But it will be especially beneficial to such extent as it can be done. When so applied, the leaves, merely as covering, protect the wheat from being killed by the winter's cold, and from violent alternations of temperature. And they do the same for the clover sown afterwards, and also protect the young plants by shade and moisture. And besides these merely mechanical modes of action, the leaves serve as well as manure, both to the wheat and to the clover, as they could in any other mode of application. An important objection however to this mode may exist if the leaves serve to shelter and protect chinch bugs, as coarse farm-yard litter does, if thus laid on wheat, when those destructive insects are numerous.

Two other modes of top-dressing have been practised and approved by good farmers, in different parts of Virginia. The first is of well-rotted manure, applied on wheat during winter and spring. It was practised by Mr. Richard Sampson, and his account of it may be seen at page 58 vol. i. of Farmers' Register. The practice is doubtless good when manure so rotted is on hand, and the most convenient application is to the wheat field. The other mode, which was in use on some of the Rappahannock farms, was to apply the coarse unrotted manure on the surface of the corn-field, after the corn had been planted, or had come up. I have also practised this plan when much more convenient to do so; and would care but little to choose between this top-dressing and ploughing the manure under, before planting the corn. But neither to wheat or corn ought the top-dressing to be given, if the clover land is as convenient, and as much needing the manuring.

VII.—Rotation of crops.

One of the best indications of the agriculture of any region being in an improving state, though this improvement be not yet much extended, is the regard recently paid to the proper principles of rotations of crops. And if no regard be had to this part of husbandry, there will not be good farming, no matter what may be the goodness of the soil, or the industry and skill of the cultivator. If judged by this test, the agriculture of lower Virginia is making good progress towards an improved state, though yet very far below the point aimed at. There is no rotation universally admitted to be the best, even under the same and most favorable circumstances. But almost every intelligent farmer at least exerts his reasoning faculties on this subject, and adopts such rotation as his judgment makes out to be the best for his particular circumstances. Still, no one of even the best farmers and most successful improvers, seems to be entirely satisfied with his own system of rotation. And this very discontent serves to prove that each one is striving to find out and to pursue what is the best course, without being bigoted to even that which he so far prefers. These remarks however apply only to a few of the best farmers; who, however, as in all cases when agreed themselves as to the best courses, will serve as exemplars and guides to all others who can or will profit by any instruction or example.

The Eastern Shore two-field rotation, of 1st, corn, 2d, oats, followed the same year by volunteer Magothy bay bean, serving as a manure crop for the corn of the next (the third) year, however scourging, without great attention to manuring, is a rotation sustained by reason, as well as by experience.

The old three-shift rotation, common on the greater number of farms which have any rotation at all, or where there is any thing deserving the name of farming, is 1st, corn, 2d, wheat or oats, 3d, the field at rest from tillage, but under close grazing. This is a most exhausting course. But the same frame-work, altered only by the land being limed, regularly sown in clover on the wheat, and the clover grazed only slightly and late in autumn, and the greater part turned in for manure, is a very improving, cleansing, and altogether excellent rotation for light loams, or good corn lands. This is the rotation on the lighter of the two Upper Brandon farms, belonging to Mr. Wm. B. Harrison.

The rotation most approved, however, and most practised by the best farmers on James river, and also on the lighter soils of the Messrs. Wickham, on the Pamunkey, is the four-field rotation, of 1, corn, 2, wheat, with clover sown, 3, clover, turned in for manure to 4, wheat. This seems to be a very severe rotation, and is even so considered by some of the best farmers who pursue the plan. However, this rotation, with all the objections to it, both theoretical and practical, is connected with and serves to exhibit most admirable and profitable farming, and also improvement of land such as may well compare, in these respects, with any in this country. Such a rotation *demands*, and will not do without, a good soil, good manuring, good clover, (and therefore marling or liming, or a naturally calcareous soil,) good teams and good ploughing, and in every respect good farming. He who can meet all these requisitions will succeed admirably, both as to profit and improvement, with the four-field rotation; but if he falter in the work, he will be soon obstructed by insuperable difficulties, and be defeated, and driven from this course of cultivation.

VIII.—Implements of husbandry and tillage.

Great improvements have been made within the last 25 years in agricultural utensils and machinery. Before that time, two-horse ploughs were rarely used, and only on the few richest and best cultivated farms, for breaking lands generally, and on the rich low-grounds and perhaps a few acres more of lots, on some other farms of middling grade, as to fertility and management. On the far greater number of farms there was neither a two-horse plough, nor a mould-board plough for

a single horse. Ninety-nine acres in the hundred were broken up by one-horse ploughs; and half of the whole quantity with the trowel-hoe, or fluke-hoe plough, having cutting wings to the share on both sides alike, and no mould-board. The ploughing was rarely deeper than three inches, (often less,) and even that depth, on the naturally poor lands, often reached the barren subsoil. Harrows, and the advantages of harrowing, to get rough ploughed land in good order, which no farmer can now dispense with, were scarcely known. On most farms, the only approach to a harrow was the "drag" with large wooden teeth, used to smooth newly sown wheat land, after the seed had been covered by the trowel-hoe plough. The wheat was almost universally trodden out of the straw by horses (sometimes aided by oxen) on the earth, and out of doors. Thrashing machines, (and those very inferior, on the old Scotch plan,) were not on half a dozen farms on James river, and perhaps not thrice as many in all eastern Virginia.

It can now scarcely be conceived how land could be broken up, and left in tolerable order by such ploughs and ploughing. Nor could it be done on even the poorest land, if suffered to be at rest long enough for its surface to be clothed with grass, or the earlier and more scant growth of weeds to remain. But most of the farmers who broke up their corn fields with trowel-hoe ploughs, secured the feasibility of the process by cultivating the land in corn every other year, and grazing as close as possible the intervening years. Of course there was no turf, and scarcely a living root, on poor land. Very many did not break up the land at all, at first, but merely ran a furrow with the trowel-hoe ploughs along each of the former corn-rows, checked by similar cross-rows, then planted, and ploughed the intervals at leisure some 6 or 8 weeks after, when the corn was several inches high. Many persons objected altogether to using mould-board ploughs, believing that turning over the furrow slices would exhaust the soil by greater exposure to sun and air.

Since, perhaps the error has been in the opposite direction. Many improving farmers have been even too ready to buy new and highly priced ploughs and other implements; and there are but few who have not had to throw aside, as worthless, at least as many kinds of new implements as they have retained. However, ploughs of good construction are now in general use. Two-horse ploughs are common wherever there is any farming better than the worst; and three-horse, and even four-horse ploughs are used where the natural depth or subsequent improvement of soil requires ploughing 8 or more inches deep. Good thrashing machines, either fixed or portable, of several kinds, are in general use, except on very small farms; and many a large wheat farmer would now abandon the culture of wheat, rather than to have to return to treading out every crop, as formerly.

The processes of tillage have improved with the implements for tillage; and imperfect as both yet are, these two improvements are now more advanced than the more important improvements of the fertility of the soil, and the preservation and economy of the means and resources for fertilization.

Defects of agriculture still remaining.

What has been said of improvements made, will prevent the necessity of treating of the remaining defects of agriculture at much length, copious as may be that subject. The most important defects may be despatched in a few words, as they are either the omitting, or negligently and imperfectly executing, any such of the foregoing named improvements, as may be suitable and wanting to the particular circumstances of each farmer. But there are also minor branches of these several general subjects, and also other distinct subjects, of neglect or omission, which remain to be briefly considered.

In regard to the application of marl—although it has been more universally or generally and extensively adopted and practised than any other as new and as great innovation in agriculture, and although the unusual rapidity with which the new practice has spread, is as remarkable as the extended space of operations, still very few of those farmers who have adopted this mode of improvement have operated properly, or to half the profit that even their actual expense therein, if properly directed, would have returned. The far greater number of persons commence and continue the always heavy business of marling, without providing for it any additional force, or suspending any of the previous cultivation and full employment on their farms. Few had before been able to perform properly all the ordinary labors required; and yet they count on marling their whole farms with no more labor than was before engaged. They marl only "at leisure times;" and for want of regular and continued operations, very little can be done at all, and that little at double cost. But suppose that there were no such disadvantages, but only the slower rate of work, and that the owner of 600 acres to be marled, could cover 10 acres a-year at odd jobs and leisure times, or 100 acres by merely suspending a third of his cultivation, and devoting the labor so released to regular and continued marling. In the first case 36 years would be required to marl the whole surface, and in the latter only six years. In the latter case there would be no diminution of product by the lessened tillage, even in the first year; for the two-thirds of the first field marled would yield, in the first year, more (and usually much more) than the whole without marling. And the increased rate of product of the farm, at the end of the 6 years serving to marl the whole, would more than pay for thrice the labor usually required for the marling. The mere difference to the farmer of having his land all marled, say in 1842, or not until 1852, would be the loss of the increased product for ten years. And on most of the lands of lower Virginia, that increased product, from marling alone, would be equal to half the gross product, (or 100 per cent. on the original product,) and would amount to more in 10 years than the previous fee-simple value of the whole farm. He who has determined to marl his land, and yet delays to do it, is thereby submitting, during the delay, to a loss in every crop fully equal to all that is made on the unmarled land in tillage.

But putting aside this enormous waste of value, incurred by mere delay of operations, the marling actually done, (and at double cost, from irregular working and want of method,) does not yield

half the available returns, because of ignorance or carelessness in the application, and the subsequent treatment of the land. Frequently, the quantity applied is unsuited to the nature and wants of the soil. Sometimes, from variation in the strength of the marl, and the proprietor being ignorant of the quality, or, more often, from irregular spreading, injury is done, and loss sustained, by there being too much marl on some parts, and too little on other parts, of the same field, and sometimes even of the same acre. Again, i the time and manner of application be never so judicious, and the improved fertility be never so great at first, half the surely available future profit will be lost, if the subsequent management be as improper as it usually is in almost all cases. Under ordinary tillage and management, and a rotation merely *not* exhausting, (say the three-shift, without clover and without grazing, and very little manuring,) marling may, and probably will, give a *permanent* increase to the crops of between 50 and 100 per cent. But if clover be sown, and partly or wholly ploughed under as manure, and if the *increased* supply of materials for farm-yard manure be all used, (which also will be due entirely to marl,) these means will in a few years double the direct effects of the marl alone. The whole permanently increased product, thus to be made by the most judicious marling (and the same, it is presumed, of liming,) and subsequent operations, on the ordinary acid soil of lower Virginia, might be safely counted as four-fold the previous gross products; and a ten-fold increase of the net profit, and also of the intrinsic value of the land. Yet the loss, or failure to obtain, the much larger proportion of this increase of value is borne by nearly all of those who apply marl, because they will not attend to the properties, and the mode of operation of the manure which they are using.

Having begun to marl without any guide whatever, or source of proper instruction, except my own theoretical views of soils and manures, I have myself committed more or less of every serious error above referred to, and suffered something from every kind of loss; as well as having realized enough of every benefit promised, to know what greater and more speedy general profit a proper conduct throughout would surely produce. My mistakes and losses, necessarily caused by the ignorance and inexperience of an uninstructed novice, and pioneer in a totally new business, may serve to guard from the same all followers; and they, being so guarded, may enjoy all the benefits of marling, unalloyed by any of the risks and losses of ignorant beginners. But it is a subject of regret, and of great public as well as private loss, that the actual results are very different. It is as if each new beginner were resolved to learn nothing from the previous experience of others, but prefers to owe all knowledge to his own errors and losses.

In regard to putrescent manures, there are very great and very general defects of management. On acid soils there is excuse for neglect of manuring, for it scarcely pays the cost. But on well constituted natural soils, and on naturally acid and bad soils, after being marled or limed, too much labor cannot well be given to collecting all the farm materials for, and applying putrescent manures. But even of the quantity of materials operated on, in the farm-yard and stables, there is great waste of enriching principles permitted, in various ways, but more especially by fermentation, whether the manure be heaped, or not heaped, or carried out on the fields before rotting. And such waste must take place, if decomposition of the manure proceeds, and its gaseous products be set free, when there are no growing plants present, or not enough of them, to absorb and put to use the fleeting fertilizing principles.

The neglect of proper drainage is another great defect of our agriculture, affecting not only the profits, but the health of the lower country. On almost every farm there is something of this defect. But in the low and level lands of the south-eastern counties, the whole region suffers from excessive wetness, which might be easily removed by a proper system of drainage and of tillage suited to that object. Princess Anne and Norfolk counties might be raised from their present most wretched agricultural condition, to their proper grade of fine and productive and valuable farming lands; and even the rich lands of Elizabeth City, and the now fertile and productive farms of the more carefully cultivated and beautiful low lands of Gloucester, might yet be greatly improved in value, by more thorough and general drainage.

A great defect on almost every farm to some extent, and entirely on most land, is the neglect of grass crops for hay. Even the small extent of clover husbandry, admirable and profitable as it is, scarcely forms an exception to this defect; for the clover is turned in for manure, and rarely converted to hay. On some of the best farms, and where the benefits of clover-manure have been best known by experience, as Westover and Brandon, the proprietors deem this use so much the more profitable, that they would consider the conversion of any considerable portion of the clover crop to hay as a wasteful abstraction from the product of the field under the succeeding crops. But without undervaluing the worth of clover as manure, I doubt whether these excellent farmers and improvers do not in this respect adhere too closely to their system. Before forming the seeds, which is the exhausting part of the growth, the clover has drawn nearly all its nourishment from air and water, and taken very little from the enriching ingredients of the soil. If then the first crop were mown for hay, before the seeds had been formed, there would be the following benefits derived, at very slight cost to the land: 1st, the hay, for farm consumption, 2nd, the cutting off by the scythe and destroying all annuals not then having seeded—and the keeping down of all perennial weeds, shrubs, and bushes; 3d, the having a clean second or summer growth of clover, to furnish seed if desired, or otherwise thus made free from the smothering and sometimes destructive cover of the dead first or spring crop. Of course, the mowing should be on clover of good size, and where the coarse manure had not been applied.

But putting hay from clover aside, there is general neglect of natural meadows, and still more of artificial grasses on the low and moist spots, which would be very profitable under permanent grass, and are worth but little as arable land. Yet hay, either for sale if near to market, or for consumption on the farm where needed, is per-

haps the most valuable crop of suitable land, and certainly the crop most cheaply made. For want of attention to grass husbandry, our towns continue to be supplied with hay imported from New England—and our corn crops are stripped of the leaves for fodder, though the cost of labor so employed, and the injury to the grain, must amount to much more than the value of the fodder so obtained.

A region in which hay is scarcely made at all, and grass so much neglected, must necessarily also show poor live stock, and small profits therefrom. To both these bad courses we have been seduced by the quantity of cattle-forage furnished in the offal (shucks and stalks) of our large corn crops. But all that even this bountiful supply permits, is that the cattle may live, gradually becoming poorer, through winter and spring, and yielding through the year little or no net profit, except in furnishing supplies necessary to the comfort of the family, in milk, butter, and meat, and of manure to the land.

We raise not enough hogs, for the home supply of what is the principal animal food of the country; though this great defect is rapidly becoming less. We raise very few horses for labor. Sheep are not to be found at all on most farms, owing in a great degree to the risks they would incur from dogs. If every useless and worthless dog in lower Virginia were a sheep or a hog, the expense of maintenance would be less, and the returns to agriculture greater by many thousands of dollars, besides the rendering the raising of sheep in general safe and profitable, instead of being as hazardous as if the country were infested by wolves instead of by worthless dogs.

ON THE COMPARATIVE MERITS OF THE ISABELLA AND CATAWBA GRAPES; WITH A NOTICE OF A NEW NATIVE VARIETY CALLED THE OHIO GRAPE, AND OBSERVATIONS ON THE CULTIVATION OF GRAPES FROM SEED.

By N. Longworth, Esq., Cincinnati, Ohio.

From the Magazine of Horticulture.

I was surprised on reading a communication in your magazine, (vol. vii., p. 331,) from an intelligent gentleman at Marietta, Ohio, in which he speaks of the Isabella grape as the best native grape cultivated by them, and that they commence using it for the table as soon as it assumes a red color. I should suppose he alluded to the Bland Madeira, did he not speak of that grape in a subsequent part of his letter. I have ceased to cultivate the Isabella for near twenty years, deeming it inferior, as a table and wine grape, to most others. He gives it the preference over the Catawba, as a table grape; with us, it ripens badly, and is subject to rot, and in its best state far inferior to the Catawba, either for the table or for wine. I have had a bunch of the Catawba to weigh twenty-four ounces. I have a white variety of the Catawba, and another Catawba producing fruit a third larger than the Catawba of Adlum. I say the Catawba of Adlum, for Major Adlum was the first to bring it into notice.

I have three varieties of native grapes, which I consider far superior to the Catawba for the table. They have none of the hard pulp common to the Catawba, Schuylkill, Muscadel, and the Isabella. For the table, they are equal to the Meunier, or Miller's Burgundy, and as free of pulp. One of them, which I first met with a few years since, I call the Ohio grape. The vine is perfectly hardy, a fine bearer, has never had the mildew or rot, and the bunches very large, say four times the size of the Burgundy. I sent a bunch of these grapes to Boston, last fall, but it was too long on the road to be in perfection. I will give five hundred dollars for a root of a native grape, that in quality of the fruit and size of the bunch, shall surpass it. The other two are equally good for the table, perfectly hardy, great growers, but the bunches of fruit are not so large.

I was surprised, when east, to find no good native grapes. At my different vineyards, I have about sixty acres in grapes, but not all in bearing. Last season, I had not half a crop, with the exception of one vineyard, where the fruit was abundant and fine. I made about two hundred barrels of wine, and some brandy. I am now raising large quantities of vines from the seed of my best varieties of native grape, having cleared a piece of new land expressly for that purpose.

The Bland grape is not a native. It was introduced into Virginia from France, about fifty years since, by a French gentleman, as I was informed by Gen. Harrison, who knew the gentleman, and had seen the fruit on his table, more than forty years since. It is a good table grape, but subject to mildew, and does not always ripen its wood or its fruit. Yours, respectfully,

N. Longworth.

Cincinnati, Ohio, March, 1842.

LIQUID MANURE.

From the (London) Farmers' Magazine.

Sir,—I beg leave to state to you that, seeing the bad effects of the waste of the draining of manure heaps, and being convinced that much of the substance of the dung was contained therein, I determined on applying it as a top-dressing to a meadow, which was effected in the following manner:—Measures having been taken to prevent the escape of the water, an old tar barrel had a hole about six inches square cut out at the bung; into this was fitted a funnel made of wood, somewhat in the shape of a hopper, having the bottom covered with a piece of old tin perforated with holes, to act as a strainer to prevent straws, or any matter which would choke the passage, getting into the barrel. Two old felloes of a cart wheel, having wedged-shaped pieces nailed on the outer side at each end to keep them steady, were laid in a cart, and the barrel having a hand-plug in the cock hole, was laid on them. A trough a foot longer, the width of the cart, one side of it being bored with a double row of holes burned with a hot iron, was then slung behind, and just under the cart; which, when the cask had been filled with the dunghill water, was then driven on the meadow—the plug being withdrawn, the water flows out on the bottom of the cart and thence into the trough, which through the holes distributes it in the manner of a town watering cart. This apparatus is simple, cheap and effective; and when done with, the

trough and the barrel can be put by, and need not monopolize a wheel carriage for this particular use.

In going over the ground, the cart should be driven right up and down hill; as if it goes sideways or across the hill, the water will not flow equally from the holes, but will be in one end of the trough; and the track of the wheel points out to the driver where he is to go next turn. The effect with me has been the manifest greenness which is now apparent on all the watered parts, which show a much superior color to the adjacent spots which have not been watered, and I am satisfied that this is the most profitable way of applying that which usually goes to waste.

JANUARIUS.

DESTRUCTIVE INSECTS.

From Dr. T. W. Harris's Report on the Insects of Massachusetts.

Cucumber bug.—The pupa state of some species occurs on the leaves—of others, in the ground; and some of the larvæ live also in the ground on the roots of plants. This is probably the case with those of the cucumber beetle. This destructive insect is the *Galeruca vittata*, or striped galeruca, generally known here by the names of striped bug and cucumber bug. It is of a light yellow color, above, with a black head, and a broad black stripe on each wing-cover, the inner edge or suture of which is also black, forming a third narrower stripe down the middle of the back; the abdomen, the greater part of the fore-legs, and the knees and feet of the other legs are black. It is rather less than one fifth of an inch long. Early in the spring it devours the tender leaves of various plants. I have found it often on those of our Aronias, *Amelanchier botryapium* and *ovalis*, and *Pyrus arbutifolia*, towards the end of April. It makes its first appearance, on cucumber, squash, and melon vines about the last of May and first of June, or as soon as the leaves begin to expand; and, as several broods are produced in the course of the summer, it may be found at various times on these plants, till the latter are destroyed by frost. Great numbers of these little beetles may be obtained in the autumn from the flowers of squash and pumpkin vines, of the pollen and germs of which they are very fond. They get into the blossoms as soon as the latter are opened, and are often caught there by the twisting and closing of the top of the flower; and, when they want to make their escape, they are obliged to gnaw a hole through the side of their temporary prison. The females lay their eggs in the ground, and the larvæ probably feed on the roots of plants, but they have hitherto escaped my researches.

Various means have been suggested and tried to prevent the ravages of these striped cucumber beetles, which have become notorious throughout the country for their attacks upon the leaves of the cucumber and squash. Dr. B. S. Barton, of Philadelphia, recommended sprinkling the vines with a mixture of tobacco and red pepper, which he stated to be attended with great benefit. Watering the vines with a solution of one ounce of Glauber's salts in a quart of water, or with tobacco water, an infusion of elder, of walnut leaves, or of hops, has been highly recommended. Mr. Gourgas of Weston, has found no application so useful as ground plaster of Paris; and a writer in the American Farmer, extols the use of charcoal dust. Deane recommended sifting powdered soot upon the plants when they are wet with the morning dew, and others have advised sulphur and Scotch snuff to be applied in the same way. As these insects fly by night as well as by day, and are attracted by lights, lighted splinters of pine knots or of staves or tar barrels, stuck into the ground during the night, around the plants, have been found useful in destroying these beetles. The most effectual preservative both against these insects and the equally destructive black flea-beetles which infest the vines in the spring, consists in covering the young vines with millinet stretched over small wooden frames. Mr. Levi Bartlett, of Warner, N. H., has described a method for making these frames expeditiously and economically, and his directions may be found in the second volume of the New England Farmer, page 305, and in Fessenden's New American Gardener, under the article *Cucumber*.

The cucumber flea-beetle, above mentioned, a little, black, jumping insect, well known for the injury done by it, in the spring, to young cucumber plants, belongs to another family of the Chrysomelian tribe, called *Halticadæ*. The following are the chief peculiarities of the beetles of this family. The body is oval and very convex above; the thorax is short, nearly or quite as wide as the wing-covers behind, and narrowed before; the head is pretty broad; the antennæ are slender, about half the length of the body, and are implanted nearly on the middle of the forehead; the hindmost thighs are very thick, being formed for leaping; hence these insects have been called flea-beetles, and the scientific name *Haltica*, derived from a word signifying to leap, has been applied to them. The surface of the body is smooth, generally polished, and often prettily or brilliantly colored. The claws are very thick at one end, are deeply notched towards the other, and terminate with a long curved and sharp point, which enables the insect to lay hold firmly upon the leaves of the plants on which they live. These beetles eat the leaves of vegetables, preferring especially plants of the cabbage, turnip, mustard, cress, radish, and horse-radish kind, or those, which, in botanical language, are called cruciferous plants, to which they are often exceedingly injurious. The turnip fly, or more properly turnip flea-beetle, is one of these *Halticas*, which lays waste the turnip fields in Europe, devouring the seed leaves of the plants as soon as they appear above the ground, and continuing their ravages upon new crops throughout the summer. It is stated in Young's Annals of Agriculture, that the loss in Devonshire, England, in one season, from the destruction of the turnip crops by this little insect, was estimated at one hundred thousand pounds sterling. Another small flea-beetle is often very injurious to the grape vines in Europe, and a larger species attacks the same plant in this country. The flea-beetles conceal themselves during the winter, in dry places, under stones, in tufts of withered grass, and in chinks of walls. They lay their eggs in the spring, upon the leaves of the plants upon which they feed. The larvæ or young of the smaller kinds, burrow into the leaves, and eat the soft pulpy substance under the skin, form-

ing therein little winding passages, in which they finally complete their transformations. Hence the plants suffer as much from the depredations of the larvæ, as from those of the beetles—a fact that has too often been overlooked. The larvæ of the larger kinds are said to live exposed upon the surface of the leaves which they devour, till they have come to their growth, and to go into the ground, where they are changed to pupæ, and soon afterwards to beetles. The mining larvæ, the only kinds which are known to me from personal examination, are little slender grubs, tapering towards each end, and provided with six legs. They arrive at maturity, turn to pupæ, and then to beetles in a few weeks. Hence there is a constant succession of these insects, in their various states, throughout the summer. The history of the greater part of our Halticas or flea-beetles, is still unknown ; I shall, therefore, only add, to the foregoing general remarks, descriptions of two or three common species, and suggest such remedies as seem to be useful in protecting plants from their ravages.

The most destructive species in this vicinity, is that which attacks the cucumber plant as soon as the latter appears above the ground, eating the seed leaves, and thereby destroying the plant immediately. Supposing this to be an undescribed insect, I formerly named it *Haltica cucumeris*, the cucumber flea-beetle ; but Mr. Say subsequently informed me that it was the *pubescens* of Illiger, so named because it is very slightly pubescent or downy. It is only one sixteenth of an inch long, of a black color, with clay-yellow antennæ and legs, except the hindmost thighs, which are brown. The upper side of the body is covered with punctures which are arranged in rows on the wing-cases ; and there is a deep transverse furrow across the hinder part of the thorax.

The wavy-striped flea-beetle, *Haltica striolata*, may be seen in great abundance on the horse-radish, various kinds of cresses, and on the mustard and turnip, early in May, and indeed at other times throughout the summer. It is very injurious to young plants, destroying their seed leaves as soon as the latter expand. Should it multiply to any extent, it may, in time, become as great a pest as the European turnip flea-beetle, which it closely resembles in its appearance, and in all its habits. Though rather larger than the cucumber flea-beetle, and of a longer oval shape, it is considerably less than one tenth of an inch in length. It is of a polished black color, with a broad, wavy, buff-colored stripe on each wing-cover, and the knees and feet are reddish yellow. Specimens are sometimes found having two buff-yellow spots on each wing-cover, instead of the wavy stripe. These were not known by Fabricus, to be merely varieties of the *striolata*, and accordingly he described them as distinct, under the name of *bipustulata*, the two-spotted.

In England, where the ravages of the turnip flea-beetle have attracted great attention, and have caused many and various experiments to be tried with a view of checking them, it is thought that "the careful and systematic use of lime will obviate, in a great degree, the danger which has been experienced" from this insect. From this and other statements in favor of the use of lime, there is good reason to hope that it will effectually protect plants from the various kinds of flea-beetles, if dusted over them, when wet with dew, in proper season. Watering plants with alkaline solutions, it is said, will kill the insects without injuring the plants. The solution may be made by dissolving one pound of hard soap in twelve gallons of the soap-suds left after washing. This mixture should be applied twice a day with a water-pot. Kollar very highly recommends watering or wetting the leaves of plants with an infusion or tea of wormwood, which prevents the flea-beetles from touching them. Perhaps a decoction of walnut leaves might be equally serviceable. Great numbers of the beetles may be caught by the skilful use of a deep bag-net of muslin, which should be swept over the plants infested by the beetles, after which the latter may be easily destroyed. This net cannot be used with safety to catch the insects on very young plants, on account of the risk of bruising or breaking their tender leaves.

THE SEA DEVIL CAUGHT AT CHARLESTON.

One of the fishing boats in our harbor had a delightful excursion yesterday, without the use of sail or oars. It appears that while the persons in the boat were quietly pursuing their avocation of hooking the finny inhabitants of the deep, off Holmes' wharf, a monster, in the shape of a devil fish, became entangled in the cable by which the boat was anchored, and much to the astonishment of the crew made off with her, taking a direction down the river. Persons on board other boats observing an unusual struggling and splashing in the water, made off to their assistance, and after a hard contest of some hours, (six boats, using some twenty oars, being engaged,) the monster was brought up to town, and became an object of much curiosity, being visited by large crowds. Shortly after reaching the market wharf, it gave birth to a young one, which was landed and placed in one of the stores. The old sea devil measures about fifteen feet from wing to wing, and about sixteen feet in length, being similar in form to the Stingaree. It is supposed to weigh about a ton. The young one is about six feet by five and a half.—*Charleston Courier, 27th April.*

Devil-fish—We have examined the preparation of this enormous beast—which has been made by Mr. R. Waters—and is remarkably well done. Few persons, even here, have ever seen this extraordinary monster, and it is believed to be peculiar to our coast. Take these dimensions for instance—length from mouth to end of tail 16½ feet ; from tips of wings 18 ft. ; of mouth 2 feet 10 inches ; distance between the eyes 5 feet ; weight 3,780 lbs. Among the remarkable peculiarities of structure, may be mentioned the brain, which is small and only protected by the skin of the back—the back bone, which is solid, from the mouth to the tail ; the ribs, so to call them, which hinge in the back bone and run under the skin—about the size of the finger and elastic like whale bone—to the wing—gradually tapering as that recedes to the tail. The general shape is that of a sparrow hawk, with the wings fully extended—wanting the head and tail. The tail of the devil fish is a mere whip-cord. It is provided with a fin on the back, at the tail, which serves for a rudder.

It is not yet settled what this fish feeds on, though it is generally supposed to live by suction, notwithstanding its big mouth. It is armed about the mouth with two fin-like flappers, which are certainly the instruments by which it lays hold of the anchors of boats, &c., though it is by no means certain that they aid it in feeding. On the whole, this may be pronounced the oddest of odd fish, and well worthy of being preserved.

At the north this fish could not fail to attract the wonder of the million, for it is not found in their waters, and differs in a marvellous degree from all the monsters of the ocean.—*Charleston Mercury.*

NEED FOR AGRICULTURAL EXPERIMENTS.—COTTON INSECTS.

Extract from an Address on Agriculture, delivered before the Alabama State Agricultural Society, on 7th Dec. 1841. By the Rev. Dr. Manly.

Experiments for the improvement of agriculture, as they require, when conducted to the best advantage, considerable surplus wealth, much time, patience, and accuracy, and the highest qualities of intelligence ; and as, when successful, they issue in the most momentous results, are worthy the first efforts of genius, and the highest aspirations of patriotism.

No improvements are made without experiments. It is true, they are not absolutely confined to the rich. There is even an advantage, when practical men of limited means, who live by the returns of their labor, can be induced to try them. These will always make them on a plan in which failure will not be injurious, and success will be universally beneficial ; because the poorest may copy out the processes and realize the results. But it is a duty specially incumbent on planters of substantial independence. Some experiments, of course, will be failures ; and such are able to hazard something. The fear of being thought visionary, may deter men from a course of experimenting. And what if the imputation should actually be made ? This is what has happened to every individual who has devoted himself to the enlargement of the boundaries of knowledge. But even visionary schemers are a more deserving class of men than those who will attempt no improvement. For, from the results which they reach, though useless to themselves, wise and practical men will derive important hints ; and thus, incidentally, they do good ; while, as they never set out to get rich, their failure is the less disappointment to them, and they do not need our pity.

I must not be met here, by the inane outcry against " book-farming," and against science as useless to agriculture. I wish not to argue the question on general principles, with this class of objectors. I will advert to facts too stubborn to be overthrown,—to facts, too near the cotton planter's interests and feelings to be disregarded, or overlooked.

Every planter knows something of the depredations of the "*lice*"—the little insect that preys upon the cotton when very young, in the spring. Another familiar enemy is the worm that perforates the boll in August. Either of these is sufficiently injurious alone ; and sometimes they are both, in their seasons, propagated and carried through their transformations in the same field.

Will any planter present consider for himself what average deduction from the cotton crop of Alabama should be made, arising from these two causes ? We know that, in some seasons, the loss amounts to half the crop. And what, in round numbers, is the average market value of the cotton crop of Alabama, unreduced by the depredations of those insects ? The average crop now, is about 300,000 bales ; worth at least $10,500,000. Suppose it diminished one fourth, the average annual loss would then be over $2,600,000. This year has been much less destructive than many years are, perhaps less than the average of years. And yet a single planter of Perry county told me, a few days ago, that in this very year they had destroyed for him, at the least calculation, 400,000 lbs. of seed cotton ; worth $8,000 ! Science, it is true, may cost something, but ignorance costs much more ! We hear much of the burdens of education. But here is a clear annual contribution to *ignorance*, of $8,000 from one man ; and all the planters in the state have contributed in the like proportion.

Science spares the illiberal, the unwilling ; but ignorance, is all-comprehending, inexorable, and resistless.

Now, suppose that any foreign enemy sweeping our coast, or any savage foe lurking on our frontier, should annually levy a contribution, by open force, or secret violence, equal to the depredations of these insects, how would this be entertained ? Although but few persons comparatively were interested, every man in the state would be ready to fly to arms,—the whole power of the general government would be roused to resistance ; and neither land nor sea would furnish hiding-places so remote or obscure, nor fortresses so impregnable, as to shelter the aggressors from merited vengeance. Millions on millions would be lavished, and life profusely devoted, in the patriotic effort to arrest the depredation.

But here is a depredation, that goes on from year to year, " laying taxes without our consent," to an amount not only *indefinite, but absolutely incalculable*, upon the whole body of southern planters, and through them upon the whole union ; and yet the whole body of them, the high-minded and chivalrous, the keen and calculating, the bold, restless, and indomitable together, tamely *pocket* the affront ! The colossal, and almost resistless power of Great Britain could not collect from our feeble colonies in '76, a paltry tax of 3 pence a pound on imported tea, levied without their consent ! But here is the richest production on the face, or in the bowels of the earth, cut off sometimes, by half ; and the richest body of men that ever lived on it, foiled, discomfited, reduced to abject submission, that scarcely thinks of the means of protection, by an insect, a butterfly, a louse, a maggot !

It is already in the minds of some of this audience to say, " This is a providential infliction, and there is no contending against Providence." So are 'briers and thorns' a providential infliction ; but that is no reason why we should not cut them out of our fields. So is sickness a providential infliction ; but that is no reason why we should not seek to prevent and to cure it.

The present state of man is a state of *trial*. As there are many facilities opened up by Providence, for the purpose of trial, not to be used, but avoided; so, there are many obstacles interposed from the same source, not to discourage and thwart us, but to test our ingenuity, resolution, and perseverance in overcoming them. And this is one of them: nor could men be placed in circumstances more favorable for contending with such a foe than the body of southern planters. They have wealth, leisure, and intelligence, and have not been thought deficient in energy. The result to be reached is of such magnitude as should provoke the ambition of the most cultivated, or wealthy. The philanthropist, even, could find no field more fit for the exercise of his high powers.

Were any person possessed of the secret by which in an easy, practicable method, these enemies of the cotton plant might certainly be prevented or dislodged; what might Alabama *afford* to give for such a secret? Millions! millions!

But is it really the case that a remedy for these ills is within the range of science? True science is modest, and does not assume to itself omnipotence, nor even seek favor by boastful pretensions. An answer to that question, however, may be inferred from her achievements in kindred branches of practical knowledge, known and read of all men; and from a view of the nature of the case.

On this subject, as the humble advocate of science, I would content myself with suggesting, that it is possible to capture some of these insects, to keep them supplied, in confinement, with every thing they could find in the fields, to oblige them to carry on all their operations, and pass through all their transformations, under the scrutinizing and unremitted observation of scientific and practical men; who would mark all the phenomena, their periods, their habits, their mode of propagation, their transformations, their winter abodes, and the circumstances which give them influence.

I ask now any plain, common-sense, unlettered farmer, if there is not a glaring probability that such investigations, persevered in, might give the planter a hint by which he could adopt means, at least for the mitigation of the evil, so as to render it comparatively harmless?

* * * * *

Who will deny the possibility of success, in the instance of the cotton insects? We are sure that ignorance and inactivity will not find a remedy: *perhaps* science may. And the whole cost of the experiment for all time will not amount to the tenth part of what ignorance is now levying upon us, year by year!—It may cost the expense of an experimental farm, with suitable buildings, appurtenances, and apparatus. It may cost the means of engaging the services of some four or five scientific men, skilled in natural history and chemistry; practical, laborious pains-taking men, who will be exclusively devoted to all inquiries affecting agriculture, joined with a communication of a thorough professional education, manual and intellectual, to all classes of our young men, who intend to be planters It may cost this; the setting apart, in a permanent investment, of some $250,000 perhaps, of the people's money, to do what may be styled, if ever any thing on earth could, *the people's own business.*

Could we even suppose it probable that the experiment would fail as a means of extermination of the insects in question, can any reasonable man doubt for a moment what would be the effect on the general interests of agriculture, of such an establishment? A body of able men professionally and exclusively employed in applying the deductions of science to the actual tillage of the soil, to the developement of all its adaptations and resources in every part of the state, to the suggestion and proper trial of every species of improvement in all the productions and arts of husbandry, to the training up, by the union of study and personal labor, of a race of hardy, virtuous, enlightened cultivators of the soil,—the foundation and defence, the bone and sinew, the right eye and arm of the commonwealth?

Gentlemen, it is too plain to admit of a doubt, that such an establishment would, in the course of fifty years, repay to the state in one form or other the cost of the investment, *one hundred times over.* * * * * * * * *

REPORT OF THE CUMBERLAND AGRICULTURAL SOCIETY ON GYPSUM AS MANURE.

To the Editor of the Farmers' Register.

By order of the Cumberland Agricultural Society, at their meeting in November last, the following report is sent to you, with a request that you will give it a place in the Farmers' Register.

Very respectfully, THE COMMITTEE,
BY J. MILLER.

May, 1842.

The committee appointed, by a resolution of the society, to report, "on the benefits of gypsum or plaster, the time, manner, &c., of applying it, to what crops, and on what soils it is most beneficial, and all other information in relation to the subject which they deem important," have had these matters under consideration, and respectfully submit the following report, in part. They say in part, because, as presented to your committee, it is a most fruitful theme, requiring a degree of labor and research which they have not had time to bestow. But such information as they possessed, or have been able to obtain, they freely communicate to the society, as far as they have had opportunity to embody it, feeling very conscious at the same time, that they are communicating little or nothing that is new or valuable; and still more, that they possess no talent for giving to old thoughts a new and pleasing dress. To enter into a formal argument, at this time of day, to maintain the general proposition that plaster of Paris is beneficial to the agriculturist, would prove us a century behind the age in which we live. It is, therefore, presumed that such was not the intention of the society in the reference of this subject to their committee. Assuming this position then as granted, we proceed to the other subjects of inquiry presented by the resolution, not confining ourselves to each in order, but treating them indiscriminately, as they most naturally suggest themselves to our minds, yet, as we trust, intelligibly. Premising that this valuable article can now be procured in our neighborhood, from Stony Point mills to Farmville,

ready ground for use, at $12½ per ton, the farmer taking it away in his own vessels, or at $14 barrelled up, or that it can be got up in the lump, at 9 or 10 dollars, and pounded, (the comparative benefits of which are in a course of experiment by our worthy president, and others near us, the results of whose experience we shall doubtless soon know,) we express it as our opinion that half a bushel or a bushel per acre, prepared in either way, and judiciously applied, is of more benefit to the land and the crop than five times the same quantity of any other manure within our knowledge. To realize all its advantages it must be applied to a clover crop very soon after the removal of the crop of wheat or oats, or the following spring, or both, (February or March is the best time for applying it the second year,) that is, where the clover is the crop for the benefit of which the plaster is used,—or to a clover lay about to be turned in as a manure for some other crop,—or to a coat of vegetable matter or coarse manure about to be ploughed in for the same purpose,—or on checks or drills of manure, especially of coarse manure, on which you are about to hill or bed the land for a crop. The application of it first recommended would, we are persuaded, save many a field of young clover which perishes, in dry seasons, from its sudden exposure to the hot summer sun, after the removal of the crop of small grain which had protected it during the earlier part of the season. We regret that we have no experience of our own to adduce on this branch of our subject; but we learn through one of our body, in habits of intercourse with the farmers on James river, below Richmond and Petersburg, that such is the practice with some of them, and with marked improvement of the clover and the land. We add that, admitting its benefit to clover at all, (on which surely we are all agreed,) this conclusion, we should think, would address itself at once to the understanding, too powerfully to be resisted. A practical farmer, of no ordinary merit, in an adjoining county, mixes his plaster with his clover seed when sowing, in the proportion of a bushel of the former to a gallon of the latter, with the same result. A question has been started whether its application to wheat at that stage, may not increase its tendency to rust. We merely throw out the idea to set wiser heads to thinking, without expressing an opinion upon it. If aught, however, which may add to the sap of the wheat, when there is danger of redundancy, and consequent danger of rust, should be avoided, then it is worthy of some consideration, especially when the wheat crop has, for years, been so precarious, and more perhaps from rust than any other cause. And if the clover and the land can get the full benefit, and an injury to the wheat be avoided at the same time by sowing the plaster after harvest, rather than with the clover seed, certainly it should be done.*

2dly. On clover the second spring. This being the universal and approved practice, where clover is plastered at all, it needs but a passing remark or two. In vain do we sow plaster, if we tread or graze our clover the same winter or spring. Not a hoof should go on it after November. Nay, we doubt whether, if it could be avoided, our young clover should be grazed at all. But we will glean our fields of the scattered wheat and oats; and it would be darting straws against the wind to argue against it. Some judicious James river farmers, it is true, recommend that it should be grazed the first summer and fall to cleanse it of weeds, especially the stick weed. It is very questionable, however, in the opinion of your committee, whether, upon our drier lands this should be done, except, as before intimated, it will be very sure to be done "right or wrong." But when we have gleaned our fields, if we would preserve our clover, or profit by it, and at any event by or after November we must provide pasturage for our stock elsewhere. But what, it may be asked, has this to do with plaster? Much every way. We are required to report on the time and manner of applying it. We answer, in this connexion, sow it on young clover in the spring, not trodden or grazed since the preceding November, for a crop of clover. If you first lighten the soil with a thin, sharp coulter, (supposing it at all close,) you would perhaps do well. February is the best month for applying the plaster; March will do, but not as well.

3rdly. Apply it, half to one bushel per acre, to a clover lay, to turn in for the benefit of some other crop. Many planters, it is believed, keep up their tobacco lots in this way, without deterioration, with a rotation of tobacco, wheat and clover. This, in a tobacco district, is perhaps the most profitable use to which plaster can be applied: and in the spring for tobacco, as late as April, or even May; for corn, as late as March, or 1st of April. In one instance known to your committee the present year, a clover lot was thus prepared for tobacco as late as the 21st of June; and the crop compares advantageously with lots highly manured from the stable and farm-pen. In another instance, where a luxuriant growth of clover was turned in late in February and early in March, without the second plastering, but well plastered the spring preceding, a very heavy crop of tobacco, and of superior quality, is the result. The land has undergone a pretty severe course of cropping since it was cleared, some 9 years ago, viz.: three crops of tobacco, then wheat, clover and tobacco twice; and has been fully kept up to its original fertility, if not improved, by this system of clovering and plastering. Nay, it is believed that the tobacco crop on it this year is the best it has ever produced. These, with many other instances which might be adduced, within our own experience and observation, as well as upon the information of others, convince us that the spring fallowing of clover land, intended for a hoe crop, is better than fall fallowing. But if the planter has more of it than he can do in the spring, or deems it unsafe to defer so much of his ploughing to such a late period, his clover lots intended for tobacco, at least, should be broken up in the spring, with the previous dressing of plaster recommended. The second instance, above referred to, goes far to prove the continuing be-

* Since the foregoing part of this report was written we have conversed with an intelligent planter and farmer of this society who insists that the chief danger to the young clover arises from the great draught on the land by the wheat crop from April to the time of its maturing, and that therefore the best time to sow plaster to obviate if is in April. And, in the single instance in which he tried it, he thought the clover greatly benefited, and that the wheat received no injury.

nefit of the plaster after the first year; and is only one of many going to establish the same fact and giving us assurance that its advantages are not limited to a single year, or single crop, but that, directly or indirectly, it imparts additional fertility to the land for years.

4thly. Apply it in the same mode and quantity to any coat of vegetable matter, or coarse manure to be turned in for a hoe crop. As facts speak louder than mere speculation, we state that one of your committee, some years ago, sowed plaster on half rotted wheat straw, with which he manured part of a tobacco lot, and gave the remainder of the lot about the ordinary coat of farm-pen and stable manure, without plaster, the advantages of the different parts being, in all other respects, about equal. The plastered part was the best tobacco. The peculiarities of the season are not now recollected. He would, by no means, recommend this example to the imitation of his brother planters: it was a last resort in his case, his better manures being exhausted. But what would probably have been the effect of plastering the whole?

Another of your committee, in the year 1836, cleared up a piece of old-field pine land, set with broom-straw, and other coarse grasses and weeds, and partially covered with pine leaves. The land was very poor. He took off only the wood, and such coarse litter as could not be ploughed in, sowed plaster in the spring, ploughed it in, and planted corn. The crop was a fine one for the land, not less than 6 bushels to the acre—while a part of the same land, left unplastered for the sake of the comparison, yielded only 2½ bushels to the acre. The same land now, from the use of plaster and clover, yields 3 or 4 barrels to the acre.

Another member of your committee sowed half a bushel of plaster per acre, on part of a tobacco lot late in April, which had been covered in February by a heavy manuring on clover; on another part, having twice the quantity of manure, but no clover, 1½ bushels. The clovered part made the best tobacco.

5thly. It would seem almost superfluous to say that if plaster acts so kindly sown broadcast on such manures, it must act, with no less effects, on hills or drills of the same. This perhaps may be the more economical way of using it, viz.: checking the land, where to be applied in the hill, and depositing the manure and a table-spoonful or two of plaster in the check, and hilling on the check. Where to be drilled, make a small furrow, deposite the manure, sow the plaster on it, (as much per acre would be required in this way, perhaps, as sowing broad-cast,) and bed the land upon the drill. A very judicious cultivator, a member of this society, being asked by one of your committee, how his tobacco came to be better than most of his neighbors', on land apparently as good, and as well manured? What secret he had, if any, in the preparation or application of his manure? Replied that he had none, unless it was that he drilled his manure altogether, and that not in furrows, but upon the slightest perceptible line, or mark made with a trowel-hoe, the ground being first well prepared; the advantage of which, he said, was to bring the manure sooner to the nourishment of the young plants, at the very stage that they most need it. He was not asked, whether he plasters those drills of manure. Most probably he does, as he uses the article to some extent. But whether he does or not, it would no doubt improve the crop, as well by bringing the manure sooner into action, as by its own magic influence, and perhaps the crop of small grain to follow, and the land.*

6thly. Rolling seed-corn in plaster, or putting a little in the hill when dropping the corn, sowing it lightly on tobacco plants, in the bed or patch, especially when they appear faded or sickly, on plants in the hill at almost any stage, but especially just after trimming down, and just on the eve of a rain, if you can so time it, and soon after topping, are modes of using it with which, it is presumed, most planters are familiar, and the advantages of which they generally appreciate.

7thly. It is recommended by respectable authority, known to the committee, and by Liebig, in his "Organic Chemistry," to use it in the stable, farm-pen and manure bank, by mixing a small quantity with the contents of the stalls, pen or bank, to which it is said to give much greater activity. While we have no experience on this subject, this use of plaster commends itself so powerfully to our reason, and is attended with so little trouble and expense, that we think the experiment worth trying.

On the question "to what soils it is adapted?" we would say that, in our judgment, it is as well adapted to the soil of Cumberland as any whatever. On light, gray land, the general character of ours, where it has not been worn out, with the least mixture of vegetable matter, it acts like a charm. And even where such land is pretty well exhausted, if it has a tolerable subsoil, it is perhaps more easily resuscitated than any other, by the judicious use of clover, plaster and manure. The red lands, stony lands, stiff low-grounds, and creek and branch flats, generally of vegetable mould, or made earth, as we say in common parlance, and even pipe-clay lands, which form the exceptions to the general character of our soil, admit of the most profitable use of plaster. It tells on clover, especially, grown upon red land, as decidedly as on any other. An opinion is prevalent with many, that it does not act kindly on what we call pipe-clay lands, and perhaps it does not as much so as on others. But we are persuaded, that where it has failed of a happy effect on such, or on any, it has been more owing to the land not being well drained, or destitute of any vegetable matter to help it along, if we may so speak, than to any natural incongruity between the land and the plaster. It will not act on a mere caput mortuum, (naked clay) or on sobbed land, however well supplied with vegetable matter. But very striking effects from it are seen on well drained low-grounds of this very kind. The James river bottoms, for example, have generally the subsoil, which gives

* Since writing the above, one of your committee has seen a gentleman who manures for tobacco in this way, *including the plaster*, and who says that the result is superior to that arising from nearly double the quantity of manure spread in the usual way and ploughed in. It cannot admit of any question, however, that the latter would be better for the crops of wheat and clover to follow.

this designation to land. Yet where shall we look for more wonderful results, wrought by the judicious use of plaster? On all lands, then, we would say that it acts beneficially, with the proper accompaniments; and that the Cumberland agriculturist, especially, has great encouragement to try it. And so of crops, the difficulty, in the opinion of your committee, would be to say what it will not benefit, from our most valuable staples, down to the smallest garden vegetable or flower. But its adaptation to clover has been probably the best tested, and its continued application to that crop is yet, we trust, to produce the most marked results, in reclaiming our exhausted, and preserving our rich lands. To other grasses, to corn, wheat, tobacco, oats and peas, it may doubtless be applied, if not with equal, with very encouraging success. All which is respectfully submitted by your committee.

AGRICULTURAL CONDITION OF PENNSYLVANIA.

Extract from the Transactions of the New York State Agricultural Society.

Pennsylvania, in a geological sense, is characterized by a division of secondary and transition formation, excepting a small portion of primitive, in the southeast end of the state. Some geologists contend that we have no well defined primary rock, in the whole state.

While the population continued more sparse, it was not uncommon to see large portions of thin soil run over by the French pioneer system: which, failing to produce on their depleting plan, after a series of crops, was thrown out as commons, or old field. It is matter of interest now, with a more dense population, to see those commons enclosed, and made productive, chiefly by the free use of lime. This manure, being spread on the surface, has sufficient specific gravity to work in; after one or two years, the ground is cultivated, and a rotation of crops commenced. Lime, on these soils, is so effective, that the farmers count on an extra bushel of corn for every bushel of lime. Here I allude, of course, to the poor lands, destitute of carbonate of lime and the constituents of the cereal grains.

The farmers of New-York may form some idea of the use made of lime here, as a manure, when I state that I burn at my own kilns, only three in number, containing from ten to fourteen hundred bushels each, about 40,000 bushels in a year, and there are in the neighborhood some half dozen persons who burn a like quantity; some of which is hauled more than thirty miles, into the southwest of Chester county, and to Cecil county, Maryland. Lime is usually applied, at a rate from thirty to fifty bushels on poor lands, and from sixty to one hundred bushels, on good limestone land. The former practice, of spreading it fresh, in its caustic state, on ploughed ground, preparatory to planting or sowing, is fast giving way to the plan of throwing it in conical piles, to slake and carbonate, after which it is spread on the sod, as a top dressing for permanent pastures, or to lie a year or two, before the ground is ploughed. Lime at the kilns here, is sold at ten to eleven cents per bushel, and as high as twenty-six and eight cents, delivered thirty miles. The value of our first rate land in this county, may be stated from $100 to $120 per acre, according to the value of improvements, convenience, water, &c.

In Pennsylvania, it may be said there are three different systems of husbandry practised.

1st. The cropping system; the usual custom is, to plough a sod field, in the fall or spring, for corn, which is cut up at the ground, following crop oats or barley, then manured and put in wheat; after which it is put down to grass, generally clover, without and with timothy. Clover fields are usually ploughed and sowed in wheat, and make the most certain crop; the following crop, if manured, wheat, and if not, sowed in rye and seeded down to grass. This system is the most laborious, hence it is uniformly adopted by the German farmers, on our best lands.

2d. A mixed system. This system is being adopted in some sections, suitable for it. A portion of the farm is set apart, well watered for permanent pasture, which receives a triennial top dressing of lime, compost, or short manure. Green grass (Poa viridis) naturally obtains, on our strong, calcareous soils, when not broken up by culture, and is decidedly the best grass for fattening. The balance of the farm is conducted, in all respects, as stated in the first named system. This plan I consider *best*, and of course adopt it on my own farm.

3d. This is called the grazing system, and is uniformly adopted, in the eastern counties, near Philadelphia, for dairy purposes and feeding off cattle for the shambles. There is very little farming or ploughing done in this system; merely enough grain raised for the consumption of the family and stock; balance of the whole farm is appropriated to pasture, and hay. Few horses are kept, where this system prevails, oxen being substituted, on the score of economy and profit.

In some of the extreme western counties, stock raising is made the principal business, particularly in Green and Mercer counties, the soil there being adapted to grass. The stock, cattle and sheep are driven east, and sold in Lancaster and Chester counties, to be fed off.

Western Pennsylvania is rapidly improving in agricultural products; raising, according to the late census, about 2,000,000 bushels more wheat in a year than eastern Pennsylvania; the extent of wheat land being far greater west, than east of the mountains. Western Pennsylvania was formerly poorly cultivated, but is now rapidly improving and will far excel us, here, in the eastern part. While we, here, are confined to the Philadelphia market, they of the west have the choice of Philadelphia, Baltimore and Pittsburg, by canal and railway, while the Ohio and Mississippi bear away much of their surplus produce to New-Orleans.

Beet and turnip culture was commenced in this state with considerable spirit, but few continue now to advocate root culture, further than potatoes; like, *and indeed* not unlike, the multicaulis mania, our shrewd and more discriminating farmers allege that both have proved to them, like "faith without works." Draining and reclaiming bogs and swamps, afford another resource, to us, which our

forefathers overlooked, which we find best performed by operatives fresh from the Emerald Isle.

REPORT TO THE STATE BOARD OF AGRICULTURE,

ON THE BRANDON FARMS.

By Edmund Ruffin.

General description of the alluvial and low lands of a part of James river.—The low-grounds or alluvial lands on the tide-water of James river are of two distinct kinds, and both of them very different from what are usually called "low-grounds" on that and other rivers and smaller streams above tide. In all the latter cases, great as is the diversity of soils and their conditions, there would always be understood to be a general agreement in these characters: soils having been formed by the deposites of overflowing freshets, to which the lands are still more or less subject—being wet enough generally to need draining, on account of springs, as well as of inundation—and rich and well constituted as to their earthy, as well as alimentary ingredients. The low or alluvial lands of the tide water of James river, especially from Curles Neck, in Henrico, to Jamestown island in James City county, inclusive, are either of *recent* or of *ancient* alluvial formation. The *recent* alluvial, are the marshes, still subject to be covered by tides, either of common or uncommon height. These lands contain scarcely any silicious sand, and their only earthy ingredients are such as would remain long suspended in slowly moving waters, and subside slowly where the water was still, or the least agitated. Of course, this deposite is still and continually going on, and will continue as long as fine earthy and putrescent matters are washed from the higher country, and brought down by the river. Half the weight and perhaps nine-tenths of the bulk of such soils consist of vegetable matter. But as rich as they are, even the highest of these lands are worth nothing for tillage, and scarcely any thing for grass and pasturage, unless embanked from the tide as well as being drained. And when so embanked, and made dry enough for tillage, the vegetable and putrescent matter, and of course much the larger portion of the soil, run quickly into decomposition, (from which they were protected before, by being continually covered by or saturated with water,) and the land actually *rots away*, until its surface has been reduced so low, that it has became again too wet for cultivation, or even for good grass; when the wetness will again protect the remaining soil from further waste. All the many and very expensive improvements of such lands, by embanking and draining, after a few years of luxuriant and heavy products under tillage, have been lost, and the lands have become again, as at first, worthless for agricultural purposes; and, by loss of their former height, and of their previous fine growth of trees, (if the land had been high enough to bear trees,) these embanked lands, when again yielded to the dominion of the tides, are greater nuisances than before. There is scarcely an estate having such land attached, which would not be made more valuable by the total removal of the marsh. And if all the tide-marshes on the river and its creeks could be sunk twenty feet below the lowest tide, it would be almost as great a blessing to the proprietors, and to the neighboring residents, as would be the draining of all the mill ponds. The marshes, however, as a source of disease, bad as they may be, are exceeded in that respect by the mill ponds. Of course, the river farmers rarely derive any substantial benefit from these marshes, to counterbalance their ill effects.

The only other kind of what may be considered as low-grounds are also manifestly of alluvial formation, but of a time very remote, and when the waters which deposited these lands had an elevation, a volume, and degree of rapidity and power, very far exceeding those of the river now. Generally, where the lands (other than marshes) do not exceed 20 feet in perpendicular elevation above high tide, and are moderately level, they are of this ancient alluvial formation. They are scattered at intervals along both sides of the river, but much the larger part on the northern side, in detached pieces, varying in size from less than 100 to several thousands of acres together. Such lands were at first among the richest of lower Virginia, and for their valuable qualities and general advantages are still among the most desirable farming lands in our country. The well known and valuable farms of Curles Neck, Shirley, Eppes' Island, Berkeley, Westover, Weyanoke, Sandy Point, and Jamestown Island, on the north side of James river, and of small parts of Jordan's Point, Flower-de-Hundred, and all Brandon, on the south side, as well as other tracts less known to the writer, are of this particular formation and character. And though varying greatly, in many respects, they all possess a general uniformity of aspect and of quality, which distinguish them from all other neighboring lands. These general remarks are but prefatory to the particular subject of this report, which will be the two Brandon estates, in Prince George county.

The Brandon lands.—Brandon *Neck*, (the old and still usual name for all bodies of land thus stretching out into the river,) is a broad and low-lying peninsula, formed by James river and Chapokes creek, and contains several thousand acres of land, distinctly marked from the very poor and high table lands, that lie immediately adjoining. The whole "neck" embraces not only the two estates of Upper and Lower Brandon, which alone will form the particular subject of this report, but also two smaller farms adjacent, of inferior soil, and to which no farther reference need be here made. Thus the name *Brandon* has several different applications, which should be borne in mind, to prevent confusion. The whole peninsula is called Brandon *Neck*. Brandon, simply, was the one estate formerly held by Benjamin Harrison, and which, after his decease, being divided between his two sons, George E. Harrison and William B. Harrison, the two separate properties are now known, the former as Lower Brandon and the latter as Upper Brandon. The terms lower and upper have no reference to the elevation of the surface, but merely to the relative position of the lands in regard to the river. These two estates are each divided into two separate farms; and

the four farms together take in much the greater and also the most fertile part of the whole peninsula.

The Brandon lands have the same features that distinguish all the *ancient* alluvial lands of James river in general. The surface is abundantly level, yet not entirely so any where; but gently undulating, so as to be almost every where quite free from the usual evil of rich low lands, excess of water, from which these lands would have been mostly free, even without any draining. But still there was much that required draining, and which, by that mode of improvement, has been rendered as dry as the higher part. The surface of the land is in the form of many low and long knolls or broad ridges, gently sinking at their sides and terminations, and separated from each other by shallow and narrow depressions. These depressions, for want of sufficient outlets, were originally ponds, covered with still and nearly stagnant collections of rain water, either during part or all of the year. But there was very little of spring water, or other than surface or rain water, to be removed, and of course the draining was easy and effective.

The soil in general is a reddish-brown loam, well known by the provincial term "mulatto land." The soil is deep, and the sub-soil so little different from the soil in general appearance, that it may well be supposed to have been of the same formation by deposite from the same originally overflowing waters. The texture of the soil varies, in different parts, from clay loam to very sandy and light loam. But, as all know who are acquainted with "mulatto soil," the stiffest is not too stiff and intractable for easy cultivation, or too close for the profitable growth of corn; and the most sandy, if properly constituted otherwise, is not too light and open for wheat or clover. The peculiar value of "mulatto land," and which value belongs to all the tracts named above as of ancient alluvial formation, must be owing to a happy combination of lime and oxide of iron, with the other ordinary ingredients of the soil. All these lands, like Brandon, were doubtless originally very rich; and though since greatly worn and exhausted, and reduced low in product, can be easily brought back, by judicious management, to a high state of fertility. There is no *carbonate* of lime in these soils, however, (which deficiency is almost universal in eastern Virginia,) but the lime in some other form of combination must be in sufficient quantity to give to the soil the power to combine with and retain putrescent manures —to produce clover to some extent and profit— and to receive benefit to clover from gypsum; neither of which three qualities belong to any of the naturally poor lands of the tide-water region of Virginia. On the other hand, there was not enough lime naturally, in the Brandon and other similar soils, to forbid the growth of sheep-sorrel, (*rumex acetocella*,) and poverty grass, (*aristida gracilis*,) when reduced to poverty, nor to prevent there being produced great and marked improvement when more lime is given to the soil. Indeed, it is almost exclusively on this kind of land that have been made the great improvements by liming, and by clover and gypsum in connexion with and after liming, on the lower James river. There is no reason, in the character of the soil, why the use of lime should have been so far almost confined to these lands. But there were two other reasons why the use should have been first commenced there, and the improvement prosecuted with more vigor than elsewhere. The first reason was, that these lands are altogether deprived of marl, which is so generally in abundance under the hilly or high and poor lands adjacent. In the second place, these fine lands were mostly held by wealthy and intelligent farmers, and such are more capable of appreciating proposed improvements, and more able and ready to execute them.

The former ponds, though having now been for a long time as dry and as regularly and as well cultivated as the originally dry intervals, are altogether of different soil. They are of a whitish gray clay, extremely intractable and difficult to pulverize and to keep in good tilth. Notwithstanding all the greater labor and more manure bestowed on these places, they are still easily distinguishable when ploughed, wherever seen, and exhibit a manifest difference in color, as well as inferiority in texture and in product.

For the foregoing general remarks, and for any errors therein, the reporter is solely responsible. In the following statements and details of facts, and the opinions expressed thereupon, he had the benefit of the careful and well weighed information of Mr. W. B. Harrison, the proprietor of the Upper Brandon estate, in answer to particular inquiries made in person, and in free conversation. The inquires were directed generally and more especially to the subjects indicated in the circular of the Board of Agriculture; and the answers of Mr. Harrison, in regard to the Lower Brandon estate, were all concurred in by his nephew, Mr. George Taylor, the administrator of the estate, who resides there, and the investigation was aided by his more particular acquaintance with the minute details.

Where the answers or statements are general, or not specially applied to any one locality, it will be intended to suit the two estates in general. When it is proper to distinguish between different parts, the distinction will be made. The statements will be arranged under separate and appropriate heads; but the consideration of some subjects will necessarily be somewhat intermingled with others; and therefore strict regard to method and general arrangement will sometimes be made to give way to convenience for description.

After a long course of exhausting and generally injudicious cultivation of the two Brandon estates, during the minority of these proprietors, the elder, George E. Harrison, whose lamented death occurred in 1839, came of age, and took charge of his share, Lower Brandon, in 1817, and William B. Harrison two years later. Both these gentlemen have been, from the outset, devoted, judicious and enlightened farmers; and on few estates, if any in Virginia, has there been more of valuable and productive improvement made, accompanied by securing of good and increasing annual profits. The untimely death of George E. Harrison did not, as is usual in such cases, put a stop to the then well advanced progress of improvement on his estate. His property was placed, and has since continued, under the general supervision and controlling advice of his younger brother; and the same mind and spirit, with equal zeal and energy, have since

animated and directed the whole procedure on both the estates. From their contiguity, their similarity of character and of management, the two estates, large as they are, may be properly and conveniently treated of as one subject, as will be done in this report. The elder brother had lost no time, and of course led the way in the work of improvement. His whole course of operations was judicious and admirable, and highly successful. Still he was cautious, and slow in some of the measures, especially in the main one, liming, compared to the later and better assured subsequent operations of his younger brother.

When the reporter recently looked over the Brandon estates, and with more care than on former occasions, for the purpose of preparing this report, there was one thing that frequently occurred to his observation. This was, that every particular operation was directed with a strict view to economy, so that it should yield the greatest possible profit; and as there are necessarily many more things to be done than can be effected, the most desirable and profitable are chosen to be executed, and are well performed, and the less profitable are entirely neglected. There seemed to be nothing done (of farming operations proper) merely for better appearance. Where the land was rich and well tilled, the crops heavy, and every thing essential thereto well attended to, there was necessarily to be seen, in perfection, the more prominent features of the beautiful as well as the useful of agriculture. But at the same time, the less important matters neglected, because something must be neglected, (but which a martinet farmer would have removed, though perhaps at greater loss than profit,) often caused apparent defects, which some persons might deem too great to be thus justified, and even approved, as parts of the whole management. Still, whatever of such deficiencies may there exist—showing that, as much as had been done towards perfection, much still was wanting—there was no reason to believe that the choice had not been judiciously made, both of the objects to be most cared for, and those to be attended to less, or not at all. Neater tillage may be seen elsewhere, in regard to the smaller accompaniments and finishing; and where there is less to do for the force employed, there may be fewer defects of omission in general. But, for so wide a field of operation, and for the means and force for operating, it may well be doubted whether there is any where a more profitable direction of effort than on Brandon.

Extent.—The estate belonging to Wm. B. Harrison is cultivated as two separate farms. Of these, Upper Brandon farm, (the residence of the proprietor,) has 780 acres of arable land, cultivated in turn; and no separate pasture, except Kennon's marsh, forming a point in the river of 1000 acres in extent, but of which only the margin joining with the high-land, is of any use for grazing. The great body, as of low marshes in general, is so miry as to be unsafe for cattle, and the rank cover, of sedge and other coarse water grasses, of no value for their food.

The other farm, Upper Quarter, has 650 acres of arable land, and 130 more of pasture. The pasture is of newly cleared land, and has been sown, and is partly set, in herds-grass. The only other use made of it is occasionally to sow parts successively in oats. 400 acres of wood-land are attached to the upper estate.

The estate of George E. Harrison, deceased, consists of the mansion house farm, called Lower Brandon, of 865 acres of arable land; and the Church Pastures farm, including Dandridges (purchased) 950 acres, and 30 acres of pasture land. A very large body of wood-land belongs to the lower estate—much more than is of any use. More distant, there is also a great deal of very poor forest land, which merely serves to supply building timber, and some part of the material for fencing.

Soil.—More than five-sixths of all the arable land of the two estates, taken together, is mulatto loam—varying in different parts from light to stiff loam. The sub-soil generally very similar to, but more clayey than, the soil above.

Rotation of crops.—On Lower Brandon and Church Pastures farms, the rotation is the same, of four fields; and the course of crops, on each field, is 1st year, corn, 2d, wheat, 3d, clover, and 4th, on more than half the field, wheat on clover fallow, and the remainder in clover and grazed. That part of the field of the fourth year which is not grazed, and the clover ploughed under for wheat, is selected so as to be the most convenient and suitable for the purpose.

Upper Brandon farm—in the four-field rotation of 1st, corn, 2d, wheat, 3d, clover, fallowed for 4th, wheat—except that a low and very light field of 100 acres (too light for good wheat) has heretofore been kept in a two-shift rotation, of 1st corn, 2d, at rest; but is now put under a three-shift rotation, of 1st, corn, 2d, oats, and 3d, clover, not grazed.

The Upper Quarter farm, is cultivated in the three-field rotation, of 1st, corn, 2d, wheat, 3d, clover. No grazing on either farm or field of the upper estate, except on the recently reaped wheat fields and their young clover as soon as the wheat has been taken off to be thrashed; and the older clover fields late in the year after August, if to be ploughed for wheat; or September, and later, if for corn the next year. No grazing close permitted at any time.

Thus, on the four farms, there are four schemes of rotation differing more or less from each other; there being one kind for the two farms of the lower estate, two other kinds for the two farms of the upper estate, and one other kind for the light field of 100 acres attached to Upper Brandon farm. These differences have been prescribed in part by the difference of circumstances, and there being no separate pasture land on one of the two farms of the lower estate, and but 30 acres on the other; and on the upper estate the different courses were required by the difference of soil of the several farms. The Upper Quarter is more generally of light loam, better suited to corn than to wheat. The Upper Brandon farm, generally, more clayey and stiff than the other, and better soil for wheat than for corn; though the soils of both farms are no where so light or so stiff as not to be enough suitable for both wheat and corn. But, the low light field of 100 acres, though part of the Upper Brandon tract, is a very fine corn and oat soil, and nothing like equally suitable for wheat.

Preparation for and cultivation of corn.—The lands designed for the corn fields are in several different states, according to the different rotations.

On Lower Brandon and Church Pastures farms, part of the fields for corn is of clover of the third year, grazed, and part on wheat stubble. On Upper Brandon farm, it is wholly on wheat stubble, except on the light 100 acre field, which when for corn, and also the Upper Quarter shift, is in clover of the second year and best growth, grazed late only in the second year, and not so closely but that there is still a heavy cover of the remaining clover to be ploughed under.

Preparation for and cultivation of corn.—The land for corn, of either kind, is broken up with good three-horse (or mule) ploughs, cutting from 6 to 8 inches deep. This is begun in November, and each field usually finished early in winter. The dry parts of the field are ploughed flush, (or with a flat surface,) and wherever the least inclined to be wet, in ten-feet beds. The manure from the farm-yard and stables is carried out afterwards when convenient, and ploughed in with two-horse ploughs. During the spring, the lime is put out on part of the same field; and if it be a second application, it is put to the part manured. The balance of the land, not manured, is harrowed in the spring, and once harrowing generally serves to put the ground in good order.

The flushed part is laid off for planting in checks of 5 feet by 4½. The time in which the planting is desired to be commenced and completed is between the 5th and 25th of April. From 6 to 8, and even 10 grains of corn planted at each station. It is deemed economical to give so much excess of seed, to have the fewer missing places, and the less replanting. The corn at proper time is thinned to two stalks to the station.

The first ploughing, given soon after the corn is well up, is in the direction of the wider rows (5 feet) and with two-horse mould-board ploughs turning one furrow slice from each side of the corn-row. The next ploughing is across the preceding, and generally done with double-shovel ploughs, (two-horse,) going twice to the interval between each two corn rows, which breaks the whole interval. Mr. Harrison ascribes much benefit to his practice of giving early and frequent ploughings; and would prefer to repeat the ploughings as often as every 15 days, until the tillage be completed. He usually gives four ploughings (each time crossing the last,) with the double-shovel ploughs; the last of which is begun immediately after the wheat harvest is finished, and on the lightest and most forward land sometimes before harvest. The weeding with hand-hoes is commenced after the second ploughing. A second hand-hoe weeding is given to the foul spots only.

On the land thrown into ten-feet beds, there are two corn-rows planted on each bed 5 feet apart; and the first ploughing is given as above, by turning off one furrow from each side of each row. Next, the double-shovel ploughs are used to finish the interval which is on the top of the bed, (or including in it the crown of the ridge,) and one-horse turning ploughs to plough the water-furrow intervals, throwing the slices outward from the water-furrow. The hand-hoes follow, weeding the corn and putting a little earth to the plants. These operations are repeated as wanted, and four or five such ploughings are given in all. The blades (or leaves,) of the corn are pulled off and the tops cut, as usual for fodder; and no important injury to the grain is supposed to be thereby caused; care however is taken that the operation is at the proper time—not early enough (as supposed) to damage the corn, and not so late that the fodder has become much injured by decay.

Upon expressing surprise at so much tillage labor being used, in comparison with the usage of many other successful farmers, Mr. Harrison readily admitted the greater cost of his corn culture; but maintained that the additional labor was well paid for in additional product. He had tried the cheap modes of cultivation recommended, and had even succeeded in making what would have been admitted to be very good corn with less than half his number of ploughings, and without using hand-hoes at all for weeding. Nevertheless, he is sure that more work would have made a better crop, and that his now usual additional labor would have been well compensated.

Wheat.—The turning in of the clover (which has been neither grazed nor mown,) is commenced early in August, and sometimes late in July, forming fifteen-feet beds with four-horse ploughs, on the level surface; and with three-horse ploughs ploughing on ten-feet beds – *reversing* the latter, or making the crown of the new bed, by lapping the first slices, upon the former water-furrow, and making the new water-furrows under the places of the old crowns. The ploughing in both cases is from 6 to 8 inches deep, or as deep as the teams can well draw at that usually dry season, and turning under the fall growth of clover. Linked or coupled square harrows, which accommodate their cutting surface to the uneven and varying face of the ground, are passed over soon after the ploughs, to close the seams between the slices. The like harrowing is repeated occasionally afterwards, as required for the good condition of the fallow, and even the double-shovel ploughs are used on the most grassy spots.

The seed wheat is selected carefully, thrashed the earliest of the crop, and then put away dry. The sowing is commenced about the 8th of October. The seed is prepared by being poured slowly and gradually into a vessel of water, stirred, and all the floating grains, and all impurities light enough to float, are skimmed off. The wheat is then drained, sprinkled with and rolled in fresh slaked lime. This process is believed to be an effectual safeguard against the smut. The sowing is pushed on as fast as possible, beginning on the corn-land. The corn, on the stalk, is cut off at the ground, and set up in shocks, as usual, on the wheat, rows being kept sown a little in advance of the general seeding, to set the shocks upon. The corn-land is ploughed with two-horse ploughs, the wheat then sown, and harrowed in, by passing over the coupled harrows twice, or oftener if required. The usual quantity of seed to the acre is 1½ bushels, if of the purple straw wheat, and nearly two bushels if of the larger grained turkey wheat. On the clover fallow, rather more than 1½ bushels of purple straw is sown, or full 2 bushels of turkey wheat. The latter variety is preferred for cold or stiff soils—but the purple straw is better for all other soils, and in general. The latter has been sown at Brandon and preferred for the last 15 years.

On this subject, Mr. Harrison has expressed

his opinion more fully in a private letter, subsequently received by the reporter, and which passage he will make free to quote here.

"In regard to seed wheat, not recollecting distinctly what my answers were, I would say that I greatly prefer the mountain purple straw to any other variety I have ever tried on our lands. It generally maintains its superiority here from seed time to harvest, over every other kind. There is less seed required, from the smallness of the grain, and I have observed that it generally comes up better than any other sort tried here. Although it grows very tall, my observation is that it stands better during its growth, and also in a protracted harvest, than any wheat known to me, and that there is less loss incurred in securing it. I do not doubt, however, the peculiar adaptation of particular wheats to particular soils; and on some of my own lands even, I prefer the culture of other kinds, and particularly when, from the tenacity and humidity of the soil, there is any danger of the smut. The turkey wheat is well suited to such places. Having said so much in favor of the purple straw, I must, on the other hand, admit that it is very subject to injury from the fly.

"With regard to continuing the same kind of wheat, from seed raised on the farm, without deterioration, I incline strongly to the opinion that it may be done by great care in selecting seed; which is a very important matter, and should be strictly attended to. It is said to be an excellent plan to select the earliest and finest heads, and to keep it pure in that way."

On the 15th of October, the sowing on the clover fallows is begun—believing that then commences the best and very limited time for sowing. It is important to get as much seed in the ground as possible in the next 10 or 12 days—and the facilities for much the most rapid operations are offered on the clover fallow. Double-shovel ploughs are there used to get in the seed, followed by harrows. The water-furrows are every where cleared out well by the passage of a suitable (double mould-board) plough, and cross furrows and grips (small, narrow and shallow ditches,) opened wherever needed in low places where the rain water would otherwise collect and stand in the water-furrows, to the injury of the crop.

Of late, the wheat seeding operations have been usually completed early in November; and immediately after they are done, the ploughs proceed to break up the land for the next crop of corn, which it is important to begin thus early, for the purpose of forwarding all the operations of the season. The great body of the field for corn is wholly ploughed before Christmas, or soon after. The land remains softer for being ploughed thus early, (turning under a good cover of wheat stubble or of clover in most cases,) and is the better to work during the whole of the following season of tillage, than if ploughed later in the winter. The particular attention to this important object of early ploughing, for the next crop, causes it to be late before all the corn of the crop then made is housed. No night work in shucking the corn is permitted. Most of the crop is put up at first in the shucks, and shucked afterwards, during rainy or other bad weather.

The corn for seed is selected carefully—and ought to be changed every few years. The same necessity for change exists as to wheat—though in changing seed, Mr. Harrison would still adhere to the same kind, the purple straw, for the great body of the crop.

Oats.—Not much of this crop made, and only for part of the horse-food. Contrary to the prevailing opinion, and judging from his experience, the growth of oats is supposed by Mr. Harrison to be not so exhausting to the land as that of wheat.

Clover.—The uses, and some of the after management of this very important crop, have been necessarily anticipated in the preceding statements, and under other heads.

The seed is sown between the 5th and 25th of February, on the wheat succeeding corn. It is preferred to complete the seeding on the wheat land, if possible, between the 15th and 25th of February. On the oat land, the clover seed is sown immediately after harrowing in the oats, and of course later than on the wheat land, according as the season may permit the oat seeding to be done. The quantity of clover seed given is a bushel to 10 acres. Some of the best grown clover of the first growth of the second year after sowing is mown for hay—and more would be so disposed of if it were convenient at that time to devote more labor to that object. No perceptible lessening of the succeeding wheat crop has ever been observed on the places from which the first crop of clover had been thus taken off. Except this small extent of mowing, and the partial and light grazing, within limited times, before stated, all the growth of clover is turned under by the plough, as manure, either in August and September for wheat, or in November and December or later for corn, according to the rotation of crops—the former being required for the four-shift and the latter by the three-shift courses. These remarks apply to the two farms of the upper estate. On the two farms of the lower estate, as before stated, the difference of rotation requires a practice somewhat different. There the clover is grazed close during its third year of growth on that half of the field which was not fallowed for wheat the previous year. The portion of the field thus grazed in the third year of the growth of clover, and the fourth year of the order of the rotation, as stated at its place, comes under corn the next succeeding year, together with the remainder of the field, which had been put in wheat. This course, on the Lower Brandon and Church Pastures farms, has been found more improving to the land than the thorough four-shift rotation of Upper Brandon farm; but both of them less improving than the three-shift rotation in use on the Upper Quarter farm—and this rotation, in suitable circumstances of soil, crops, &c., is preferred both for improvement of land and for annual products, to either of the other courses.

Mr. Harrison's general views of the comparative merits of the three and four-shift rotations, and with such change as longer experience had caused in his mind, have been presented at length in several communications to the Farmers' Register.* His practice, in making use of both rotations, especially when examined personally,

* See p. 464, vol. ii., and p. 241, vol. iii.

offers the best commentary on, and justification of his doctrines, in this respect. It should, however, be observed, that by using both these rotations on contiguous farms, he is enabled to obtain the peculiar benefits of each, and to avoid the peculiar disadvantages of both, better than if pursuing either one of these rotations only.

Product of crops.—The growth of wheat is subject to such great disasters, and the products of different years are therefore so variable, that even if the general average product of acres and of years were accurately stated of any particular farm, it would furnish but a very inadequate idea of the true average power for production. Thus, on a field, that under very favorable circumstances may have produced 20 bushels to the acre, in another year, of the preceding or succeeding course of crops, under an unusual (but by no means unprecedented) degree of infliction of Hessian fly, chinch-bug or rust, might yield only 2 bushels. The average of these two extremes, would be 11 bushels per acre; which, however correct as a statement of actual average product, would be altogether false and deceptious as an indication of the degree of fertility, or progress of improvement. For these obvious reasons, the reporter preferred to learn and to state precisely the *best* products of wheat on each farm, for entire crops, from which each reader may for himself estimate what may be expected on the average of seasons, or in the worst of years.

The best crop of wheat which has ever been raised on the Lower Brandon farm, was in 1838, the average of the whole being within a small fraction of 19 bushels per acre. Two thirds of the whole surface under wheat was corn-land of the previous year, and one third only was clover fallow. The best crop on the Church Pastures farm was the same year, and averaged $17\frac{3}{4}$ bushels to the acre. A general average of years and of land, on these two farms, under the rotation pursued then and since, *supposed* to be 13 or 14 bushels to the acre.

On Upper Brandon, the best crop of wheat, on all the land sown (in 1838,) was 24 bushels to the acre. The general average of seasons and of land for the whole farm, supposed to be about 15 bushels. On the Upper Quarter farm, (1838) 16 bushels average—and a general average of seasons and of land, for that farm supposed to be 12 or 13 bushels to the acre.

The reporter would here remark, that these best products are not of the best few acres, nor of even but part of a crop. They are of the full wheat crop of each farm, each including its full proportion of inferior land. As all these best crops happened to be made in the same year, on four different farms, under their respective regular modes of cultivation, and under three different schemes of rotation, it is manifest that the greater than usual product was owing to a peculiarly favorable season, and not to the superior fertility of the fields producing the best crops. Such a superiority of land may well affect the result of a single year's product on one farm only, and still more if not under a regular rotation with fields of something like equal productive value. But on four separate farms, all under their respective and regular and judiciously planned courses of crops, it would be next to impossible that there should be a general and considerable superiority of fertility found in all the fields, seven in number, in wheat in any one year, of the four farms. The reporter therefore infers that the large crops made in 1838, were not greater than may be produced in any other year of equally favorable season and other circumstances, on whatever other fields might happen to come under wheat.

All the best crops of corn were also made in one year, 1840. On Lower Brandon and Church Pastures, the crop made a general average of 7 barrels (35 bushels) of corn per acre. The general average of years, and crops of both farms *supposed* to be about 6 barrels. On Upper Brandon farm, the same year, the crops averaged in product 7 barrels, and on Upper Quarter, 8 barrrels per acre. The general average of years and crops for the former supposed to be 6 barrels, and of the latter, 6 to 7 barrels per acre.

No product of clover has ever been ascertained; but the usual growth of the best land is believed to be now, and of latter years, as heavy as on first-rate soils elsewhere, either in this country or in England. As was before observed, when speaking generally of such lands along James river, clover was raised here before liming and the other parts of the recent system of improvement had been in operation. But, (as Mr. Fielding Lewis also reported of his Weyanoke farm,*) there was no good and regular success except on the highest improved lots. Clover did not answer under general field-culture. In one of the communications to the Farmers' Register, before referred to, (p. 242, vol. iii.,) in 1835, Mr. Harrison, after having just stated that his main reliance for future improvement was placed on his expected clover crops, made the following incidental remark: "My best [clover] has certainly grown after lime and manure. *Indeed, without the previous use of lime, my clover hardly pays me for the seeding;* but in a few years we hope to have the whole arable surface here improved in that way, having already more than half accomplished it."

Liming.—This, the foundation of all other improvements on these farms, was first begun on Lower Brandon, in or about 1819, by its proprietor, George E. Harrison, who had then but lately arrived at age, and the possession of his property; but who displayed in this, as in other things, his excellent judgment as a farmer and an improver, almost from his earliest operations. The liming there was continued for some years thereafter, at what was then deemed a rapid rate, though very far exceeded since, there and elsewhere, when all early doubts of the large amount of profit had given place to perfect confidence. During those first years, the amount applied did not exceed the lime burnt from 200 hogsheads of oyster shells in any one year. Afterwards, the rate of progress was greatly increased. Before the death of the proprietor, nearly all the land of Lower Brandon and Church Pastures had been limed over once; and much of the same land has since received a second and lighter dressing. The second liming has been usually applied to the parts of the fields which had remained two years in clover, and preceding corn.

It was 11 or 12 years after the first liming on

* Report of the farming on Weyanoke, p. 17, vol. i., Farmers' Register.

Lower Brandon had been done, before William B. Harrison had commenced; but when induced to begin, by the example and success of his elder brother, and by the still older experience and more valuable lights and instruction of their old friend, Fielding Lewis, (to whom all concur in awarding the honor of being the pioneer and leader *par excellence* in this important agricultural improvement in Virginia,) the greater rapidity of progress on the Upper Brandon estate made amends for the late beginning. The liming was commenced in 1830, and both the farms had been completely limed, the first time, by 1838. The largest operation of any one year was 1900 hogsheads of oyster shells, bought, burnt, and applied. About one-fifth of the surface of both farms has been since re-limed.

The shells are brought from the oyster landings on the salt waters of James and York rivers, in vessels that make it a regular business, and are sold, on board the vessels, lying off the farmers' landings, at prices varying from 50 to 70 cents the hogshead, or 18 heaped bushels of shells. The purchaser has to take the shells from the vessel, with the assistance on board the vessel of the crew. The manner of burning and of distributing over the land pursued at Brandon is much the same as that of Mr. Lewis,* except that the kilns are put up with much less care and trouble—being merely heaps of wood and shells in alternate layers. In this manner, a cord of wood, or rather more, serves to burn 10 hogsheads of shells. By burning, (and before being slaked,) the shells are reduced in bulk about one third, or 100 bushels of shells measure out only 66 to 70 bushels. 72 bushels in this state, were put to the acre, of land ready ploughed for corn, by placing half a bushel to each check of 18 feet square. When air-slaked, and either by first covering over the heap with the surrounding earth, or without, the heaps are spread, and the land immediately harrowed, to divide and diffuse the lime properly, and mix it well with the surface soil. Mr. Harrison has made no estimate of the full cost of liming, in labor as well as money. His brother had estimated it at 10 cents the bushel, or, for such a dressing as the above at $7.20 the acre. And costly as this may seem, and alarming to the inexperienced, there is no farmer on the river who has limed to considerable extent, and in judicious manner, who does not regret (as a great and certain loss of profit in the omission,) that he did not encounter this expense earlier, or more rapidly than he did.

Mr. William B. Harrison re-limes at half the above rate, or 36 bushels to the acre; and he would now advise the putting no more than the latter quantity even for the first time of dressing, as he has seen injury produced by the too great quantity at once of 72 bushels. Decided and early beneficial effect he has always found to follow the first liming; and he has no doubt of benefit having also been produced by the second applications; but such would of course be less obvious, and has not always been observed. Mr. Harrison thinks liming to be the cheapest and best kind of manuring, counting both cost and returns. The gross products of the Brandon lands have been increased to double, since the occupancy by the two proprietors—and fully a third, in corn and wheat, since the liming. Of course, when gross products have been doubled on the same, or nearly the same amount of surface cultivated, the net products, or clear profits of farming, must have been increased in a far greater proportion.

Lime is the main source of improvement by other manuring, by its producing clover to be used as manure, and also by the farm-yard and other putrescent manures becoming much more operative on the land after lime has been applied. Of the latter important effect, no doubt is entertained. Before liming, clover was not so generally sown, and the crop often failed; and gypsum had on it but slight effect, and was not often used. There never had been a heavy field crop of clover in Brandon Neck, (though smaller spaces of the best land had sometimes produced very well,) until in 1835. Latterly and since liming, gypsum is regularly sown, at one bushel the acre, on clover, the spring (or second year) after sowing the clover. The effect is believed by Mr. Harrison to be always good and profitable on limed or originally good soil; but he is doubtful as to the unlimed, if originally poor, or even on land not of very good original quality.

The gypsum is sometimes bought ready ground, but more generally in the lump, and crushed at home, by a corn-crusher. The usual price, in the lump, is $5 the ton; but one cargo from Massachusetts was bought as low as $2.70. The ton measures 20 bushels or more when ground.

Live stock and putrescent manures.—The subject of prepared or putrescent manures cannot well be considered separately from that of the live-stock, which serve to produce so important a part of the value of these manures; and the management of the stock is a necessary introduction to the production and management of the manure.

Cattle.—There are about 75 head of cattle on each of the four farms. Their quality inferior, and their general order also, when seen by the reporter in April. The cattle on the lower estate are of better quality than on the upper. The keeping and treatment in winter are very good, so far as serve plenty of good long forage and litter, the offal of the large corn and wheat crops, and sufficient shelter from wet and cold. But this care, during all the season for keeping the cattle on dry food, does not compensate for the want of a sufficient and regular supply of good green food through the grass season. The restrictions on grazing the clover fields is one of the rules referred to before which operates admirably well for sustaining and fattening the land, but badly for fattening the cattle. The resources for the cattle, except when in the farm-yards on dry food, are the standing pasture already mentioned, furnished by the mere land margin of Kennons' Marsh for Upper Brandon farm, 130 acres of inferior land in standing pasture on Upper Quarter—and on both these farms, the grazing of the wheat field and young clover thereon for a short time after harvest, and the older clover late in the year, say in September and October. On the lower estate, also the half of one clover field on each farm, in the third year's growth of the clover, furnishes all the pasturage, except 30 acres of standing pasture on the Church Pastures farm.

* See p. 18, vol. i. Far. R. for more full description.

There being as few fences as possible (except the general outside enclosure) on both estates, there are none designed specially to separate the grazing land from the balance, and the cattle are restrained to their allotted space by being herded or guarded. This plan is however about being altered to some extent, and proper fences for the standing pastures were in the course of being constructed. This herding plan, though a great saving of fencing, and a great aid to the land, by preventing very close grazing any where, cannot be otherwise than bad for the cattle. They are harassed both by the attention and the neglect of the herd-boys—and are debarred from seeking and enjoying, at will, the full supplies of food, water, rest, and shade, that they need. Even if enjoying all these to the fullest extent for a week, the neglect or ill treatment and privation of a single day may undo all the benefit received during the week of proper indulgence. Under this plan, a stock of cattle can scarcely do well. And of these evils the reporter may presume to speak thus, as he has long pursued this same plan of herding, to save the expense of fencing—and he knows well its particular disadvantages to stock, as well as the benefit to the land and to its product. He still deems the balance of advantages greatly in favor of this plan, and it is still pursued on the farm in which he has a share, except so far as having a small enclosed standing pasture.

It is therefore by no means designed as a subject of censure, in the general, when stating the objections which apply particularly to the cattle and grazing management on the Brandon estates. The making of manure is the great object there sought and gained by the keeping of cattle; and except this, there is very little of other benefit, except that of furnishing plentiful supplies of milk, butter and meat, to the families of the proprietors, and the breeding and raising oxen for labor. There are no sales of products of stock, except about 100 lbs. of butter from the upper estate, and 150 lbs. from the lower, and some few veals from both, annually.

Horses, and stable management.—On each farm, it is made the regular business of a suitable hand to clean out and then litter the stable, and chop up the long forage, (corn-fodder or clover hay,) with a straw-cutter, and have the proper supply ready in the trough of each horse, when brought in from work, so as to save time. The allowance of corn is 5 large ears to a mule at each feed, three times a day. To large horses and unthrifty animals, more corn is given. Of the long forage, there is always an abundant supply on hand, and it is given freely, chopped as above stated. And were this allowance less abundant, more corn would be necessary.

The corn is sometimes crushed in the ear, for horse-feed, and it is highly approved. The practice was introduced on Lower Brandon by its late proprietor, and has been continued since. It is not supposed that there is any great saving in the allowance of grain—but the animals seem to thrive better, and require less long forage.

The stables are fully littered at all times. In cold weather, the litter and excrements are suffered to accumulate for ten days or even two weeks as may be most convenient. But in warm weather, Mr. Harrison deems it necessary that the stables should be cleaned out every day. For the quality of the manure, if that alone were considered, he would prefer that it should be suffered to accumulate in the stables; but the main point, whether the stables be cleared out every day or more seldom, is that plenty of litter shall be used. The fire-fanging of the manure (which is the result of too high fermentation, and too little moisture,) is especially guarded against.

There are about 120 sheep (exclusive of lambs) on the upper estate, and 140 on the lower. The sheep are herded as the cattle are, and always penned at night, and they add considerably to the amount of manure. They are fed in winter on turnips, top-fodder, &c.

There are enough hogs raised and kept on Lower Brandon and Church Pastures to furnish for slaughter annually from 70 to 80 at each farm. The hogs have a good woods range, outside of the enclosure. 58 hogs were kept up in pens throughout last year, for experiment, until killed; and the result was so favorable, that the course is continued there, and has been also commenced on the upper estate. The hogs so confined were fatter when killed, and weighed more for their appearance than the other ranging hogs. At Upper Brandon, the hog management has been very unsuccessful. Not more than about 70 hogs are killed for bacon each year. It is necessary on the lower estate every year to buy much more pork for the farm supply, besides all that is raised; and there is a still greater deficiency to supply on Upper Brandon.

The cattle are kept in the winter farm-yard through the day as well as night; and until late in the spring—sometimes until the 10th of May. The sheep, during winter, are let out of the pen to graze in the day, when convenient.

Every portion of the offal of the grain crop, (corn-stalks and wheat straw,) not required for food, is used as litter, and converted to manure. There are no other sources of supplies of litter. The wood-land is so distant that the leaves are not deemed worth being brought to the farm-yard, and there are no wet natural meadows used for mowing. All the manure made before the 10th of March, is carried out on the field for corn, (already ploughed early in winter,) and spread and ploughed under before planting the corn. When very coarse, the manure is heaped in the spring and heated a little, to somewhat rot and reduce the coarser parts. The stable manure is sometimes mixed with the poorer manure of the cattle yard, to forward the rotting. The manure made in the cattle yard after March the 10th, is suffered to remain there, and is used the next spring. This delay is deemed advantageous, as such manure is very coarse. Top-dressing on clover, for which such coarse stuff is well suited, and can be cheaply so applied, has not been yet tried by Mr. Harrison; but he will do so. From the farm-yards and stables, there were manured for this crop, (part of the late made manure of last spring, applied in autumn for wheat on clover fallow, but principally for recent manure, to corn this spring,) more than 60 acres on Upper Brandon, and more than 40 on Upper Quarter—a good heavy covering, supposed to be about 60 two-horse cart loads per acre; besides the land manured by summer cow-pens, (without litter as usual,) and which would amount to 7 or 8 acres for each farm. On Lower Brandon

and Church Pastures, about 70 acres manured on each, of farm-pen and stable manure at the above rate, besides the summer cow-pens.

Distemper of cattle.—The mysterious and deadly disease of cattle called "distemper," prevailed to such an extent in or about 1830, that 54 head of cattle, died with it on the estate in one season. The cattle that died were in good order —which is one of the peculiarities of this disease, the fat animals being more apt to be infected than the poor. Since then, cases have only occasionally occurred. Mr. Harrison thinks that the mixture of tar, sulphur and salt, kept always in the pens during summer, and which the cattle will lick, has been the preventive against this terrible disease. He was advised to use this remedy by Mr. Fielding Lewis, who, as usual, was resorted to as the best source from whence to obtain information and judicious advice. When recommending the use of this medicine, Mr. Lewis stated that, before using it himself, he had formerly lost some few cattle almost every year; but since keeping it regularly in the cattle pens, he had never lost one of his stock by distemper, except a bull, which, by being confined separately, was debarred from access to the mixture.

Laboring force of teams and hands.—On the two farms of the lower estate, there are 38 to 40 horses and mules for the plough and other farm labor, and about 48 oxen. On Upper Brandon there are 18 working horses and mules, and 15 on Upper Quarter, and about 48 oxen on both these farms also. The small oxen raised here are more hardy, and bear labor with less fatigue, than the much larger oxen of the upper country.

On both farms of Lower Brandon, there are 70 field hands of all ages and kinds. There are also 6 other men, who are carpenters, sawyers, and black-smiths. There is also a saw-mill there to provide timber and plank for the buildings and other constructions of the estate. On the two farms of the upper estate, there are 60 field hands, besides 8 mechancis, who are not employed in field labor. No domestic servants are included, nor has any reference heretofore been made to any thing of either labor or expenditure except matters appertaining to the farming operations. The splendid mansion houses and beautiful gardens and ornamental grounds, of both the estates, and every thing connected therewith, however admirable or delightful, are not proper subjects for farm reports.

Agricultural implements and machines.—The ploughs used for turning in clover to sow wheat, are the four-horse and three-horse McCormick ploughs. Two-horse ploughs, of same pattern, are used for ploughing the corn land for wheat. For breaking up land for corn, the three-horse ploughs are used. All there are made by William Palmer of Richmond.

For tillage of corn or other horse-hoed crops, on flushed land, the two-horse double-shovel-ploughs are used and preferred to all others. Single-horse turning ploughs, used for the water-furrow row (or interval) of bedded corn-land. No cultivators used. At Lower Brandon, the X plough, a kind of cultivator, is sometimes used for covering seed-wheat and oats. But if the land be in good order, the linked harrows are used for that purpose. Mr. Harrison has heavier harrows, but prefers the lighter linked harrows.

A marker is used to mark off rows to plant corn. It is like a horse-rake, except that instead of the many rake-teeth, there are 3 small iron hoes, so formed and set as to make a plain but shallow mark, as the implement is drawn across the ploughed land. One of the out-side hoes runs in the last marked row, (if on level ploughed land) and the two other teeth mark new rows. This simple implement, which the reporter saw here, and adopted its use, with some modification, long ago, offers a great saving of labor over the general mode of laying off rows, by setting up poles to direct the course of the plough.

There is at Lower Brandon a good horse machine to gather clover seed, by combing off the ripe heads, but too costly. At Upper Brandon there is a rough and simple one, such as can be constructed by any farm carpenter—and which will serve the purpose well enough.

Hussey's reaping machine was here first tried last harvest and approved, (See F. R., vol. ix. p. 434,) and it will be hereafter used for part of the reaping, unless superseded by a better.

Parker's thrashing machine, for 8 horses, is used. It has not yet thrashed out but from 300 to 400 bushels of wheat a day. But if properly fixed, and properly supplied and worked, it is thought that it might thrash 700 or 800 bushels in a day.

The straw-cutters used are Parker's.

A corn sheller, worked by 4 horses is used—and shells from 250 to 300 barrels of corn a day.

A mill which was designed by its constructor to crush and grind ears of corn for home food, is used to crush and grind lump gypsum, for manure. It will grind 40 bushels a day, with two horses, but is heavy labor.

The hand utensils are not different from those used on most other farms.

THE TIMES OF THE RIPENING OF WHEAT IN DIFFERENT PLACES.

For the Farmers' Register.

It is desirable to know the period of harvest in the different parts of the United States, and I am not informed of any tables of comparative seasons that have been published.

There is an interval of many weeks between its commencement in the southern and northern portions of our wheat growing country. The harvest begins two months or more earlier in the southern counties of England than in Scotland. The interval may not be so great here, on account of the heat of our summers even in the northern states, but yet it is so considerable that the season may operate very differently on the crops at distant points of the union.

If the editors of the several agricultural papers would make notes of the time of beginning to cut wheat in their respective vicinities it would be both interesting and useful. It would enable us to make a calculation of the effect of the weather on the crops on an extended scale, and a more general estimate might be made of the harvest than when the farmer's knowledge is confined to his own neighborhood. We should also know when to expect that the new crop from different parts of the country would be received in the market.

In the south the weather may be favorable, when heavy rains occurring after our harvest may injure the northern crop: and on the other hand rains destructive with us, may be too early to cause any damage to the north. Wet weather about the 15th June would be seriously injurious in this latitude. Five hundred miles north of us the same weather might be beneficial.

I have known incessant and great rains up to the 10th June, succeeded by fine crops of wheat.

The rains within the ten days immediately preceding harvest are the most injurious.

Sometimes a promising crop is within a few hours of being ready for the scythe, when the rust spreads over the whole of it, diminishing the product by one-half or even more.

From this uncertainty of our climate, no calculation can be made of the wheat crop till we are fairly engaged in harvest.

The following is an extract from a memorandum kept for the last fourteen years, twenty miles north of Richmond.

1828. Began to cut wheat on 9th June. Early or May wheat.
1829. June 22d, late wheat.
1830. June 15th, with a few reapers, with all hands on the 18th.
1831. June 20th, do. do. 21st.
1832. June 23d.
1833. June 14th with a few reapers, with all hands on the 17th.
1834. June 20th, do. do. 23d.
1835. June 26th.
1836. June 28th.
1837. June 24th with a few reapers, with all hands on the 26th.
1838. June 25th.
1839. June 19th with a few reapers, with all hands on the 21st.
1840. June 12th. do. do. 15th.
1841. June 23d.

The crop every year after 1828, was exclusively of late wheat, as purple straw, turkey wheat or lawler wheat. The May wheats are generally ten days earlier than the late. The extremes of the time of beginning harvest, (excepting the May wheat in 1828,) are in 1840 the 12th June, and 1836 the 28th, making an interval of sixteen days. The crop of 1840 was not a good one, that of 1836 was wretched, and in this year there was a general failure throughout the United States. The crops of 1832 and 1838 were the best of the series. We usually count on finishing harvest by the 4th July.

I hope other agricultural papers will furnish similar statements, and if none of their correspondents can go so far back, let us have at least the dates of the harvest for the present year.

Your readers would be pleased to know particularly when the harvest begins in North Carolina, Maryland, Pennsylvania, New York, Michigan, Ohio and Missouri. W.

May 29th, 1842.

We ask attention to this suggestion, and aid to the proposed measure. We will furnish our mite of practical experience thereto, very soon. —Ed. F. R.

ADDRESS BEFORE THE CAYUGA COUNTY AGRICULTURAL SOCIETY, AT AUBURN, N. Y., FEBRUARY 1, 1842.

By David Thomas.

Geologists inform us that soils were chiefly derived from the wear and tear—the disintegration and decomposition of solid rocks. In some tracts of country, the soil is nearly identical with the rock that immediately underlays it, or partakes largely of its nature; but such occurrences are rare in this county. So extremely active was the deluge that swept over and rounded our highest hills, that many a square league of stony strata was entirely buried by materials that drifted from other parts of the country, and which have no resemblance to the rocks they cover.

Favorably for the southern parts of our county, that deluge came from the north, sweeping over a limestone region, and depositing, in its course over our barren state, the rich collection it had made. And here let us stop to consider: if that flood had come in an opposite direction, bringing along the unproductive detritus of the mountains, instead of our fertile fields, and flocks and herds, we might have witnessed nothing more inviting than scrub oak plains, and a few wandering deer.

Like other floods, however, its deposites were irregular, as its velocity was increased or retarded—as it whirled into eddies, or rushed onward in its course. Pure clay, indeed, can scarcely be found in this formation; but all the varieties of loam, whether clayey, sandy or gravelly, occur; and some deep beds of both sand and gravel, are so pure as not to discolor the water into which they are thrown.

Such instances however are rare; and the grinding and mixing of so many instances by that deluge, have been eminently beneficial to our farms. No soil is fertile, says Humphry Davy, "that contains as much as 19 parts out of 20, of any one material or constituent." On the contrary, soils that contain mixtures of many things, are generally very fertile,—provided that clay, lime, and sand, form a large share of the mass. When you see, therefore, old mortar, the sweepings of the smith shop, or leached ashes thrown into the highway, you may safely conclude that the owner is greatly in want of instruction. These are excellent manures, and permanent in their effects.

Perhaps some would ask, why are different things necessary to constitute a fertile soil? Allow me to answer in the language of Dr. Jackson's Geological Report on Rhode Island; "Chemical science arranges all bodies as electro-positive, or electro-negative. The electro-positive are always the alkaline or basic substances, while the acids are always electro-negative when brought in contact with matters of the positive class. If a soil is wholly positive or negative in its nature, it fails to be fertile; and when one power greatly predominates over the other, it is not in its most favored condition. Silex is regarded as an acid, and alumina, lime, magnesia, iron, and the alkalies, are its opposites."

According to this view, the soil may be considered as a vast galvanic battery. "It is ren-

dered nearly certain," says an eminent writer, "that manures act by the salts they contain, acting when brought in contact with the earths in producing galvanic currents," and of course stimulating the plants in their growth. On this subject, however, I give no opinion of my own, because I can comprehend much more clearly, the neutralizing effects of acids and alkalies, and the absorbent powers of the different materials. This view may regulate our practice quite as well as the former; and indeed there seems to be nothing discordant between them.

It is not many years since the existence of acid soils was denied, or overlooked. The editor of the Farmers' Register, in Virginia, was the first to point out the error or oversight; and the subject is now better understood. He furnished no evidence indeed of the presence of uncombined acid; but the circumstantial evidence was very strong and pointed; and in my judgment he fairly made out his case. Since the publication of his "Essay on Calcareous Manures," other writers of great respectability have either adopted his views, or furnished additional and positive proofs of their correctness.

The question may occur, why is not an acid soil as fertile as any other? It is more fertile than any other for such plants as the red sorrel; but not for the plants which are the chief object of the farmer's culture. These generally require a neutral soil—that is, one in which lime, under some form or other, occurs in considerable quantity.

Although clay, according to Dr. Jackson's classification, is arranged as an alkaline earth, yet, as such, it is so feeble, that when united with *silica* or sand alone, the mass becomes acid, and unfitted for our usual crops. On such lands, Indian corn assumes a yellow sickly aspect, even when it is not injured by stagnant water. And what is the cure? Apply lime enough, and then, says an accurate observer, "the young corn takes immediately a deep, healthy color, before there is any perceptible difference in size. The crop will produce from fifty to one hundred per cent more the first year, before its supply of food can have possibly been increased.* And why? Because the poison which has paralyzed it, was destroyed.

It is well known that when magnesia occurs among quick-lime, it is often injurious to the land. Such a mixture is called *hot lime*, from its burning alkaline quality,—the magnesia not combining so speedily as lime does, with carbonic acid, which would render it mild. Besides, the lime, having a stronger attraction for that acid, will either be served first, or take it from the magnesia till it has got enough. I have seen spots of earth, where large heaps had been thrown down to slack, remain barren—as free from vegetation as this floor—for two or three years, although the ground had been carefully scraped over when the heap was removed.

Yet such is the stuff to which the south-eastern part of Pennsylvania owes much of its fertility. Formerly, when I lent a hand to that process, it was considered that 30 or 40 bushels to the acre were as much as the land could bear without injury. It was found, however, that rich land would bear more than poor land; and in process of time they discovered that 100 bushels to the acre might be safely and profitably applied to pastures, or meadows. The lime was slacked in large heaps; and then from a cart or wagon, on a calm day, it was scattered with a shovel evenly over the grass. It fell among the decaying leaves, which in warm weather yield carbonic acid, and it became mild without injuring the crop.

Some years ago, I published an account of this simple method, believing it superior to that of any other country, and you may judge of my surprise to see it stated in a work of high authority, bearing the date of 1840, that magnesian limestone is unfit for the purposes of agriculture!

Lime, however, possesses other properties besides that of neutralizing acids. One of the most remarkable is the power to absorb putrescent manures; and to hold the fertilizing essence till it is wanted by the crop, through every vicissitude of the seasons, and through indefinite periods of time. There it is, locked up; and nothing at common temperatures, but the energy of a growing plant, can unlock it.*

Lime has therefore been styled the basis of all good husbandry. It stores up the manure that is not immediately wanted, for future use—a kind of *save-all*. When the supplies from the barn yard are spread and ploughed into a soil that is nearly destitute of lime, the growing crop catches a part of its virtue; but a very large part escapes, and very little will be left for the benefit of those that succeed. I had been used to such soils until I removed to my present farm; and was then agreeably surprised to see how much more durable were the effects of stable manure. My fields were limed by the deluge.

Unwholesome vapors and villanous smells are also absorbed by lime; and some places, once remarkable for insalubrity, have been changed in their character by liming or marling the fields around them. Nuisances are converted into manures. A striking illustration of this principle is contained in the following account from the Essay on Calcareous Manures.

The carcass of a cow, killed by accident late in the spring, was laid on the ground, and covered by about 25 bushels of broken shells mixed with 45 bushels of earth chiefly silicious. After the rains had settled the heap, it was only six inches thick over the highest part of the carcass. The process of putrefaction was so slow, that several weeks passed before it was over; nor was it ever so violent as to throw off any effluvia that the calcareous earth did not *intercept in its escape*, so that no offensive smell was ever perceived. In October the whole heap was carried out and applied to one sixth of an acre of wheat; and the effect produced far exceeded that of the calcareous

* Essay on Calcareous Manures.

* The following extract from Liebig's Organic Chemistry, is cited as a parallel case:

"An abnormal production of certain component parts of plants, presupposes a power and capability of assimilation, to which *the most powerful chemical action* cannot be compared. The best idea of it may be formed by considering that *it surpasses the power of the strongest galvanic battery*, with which we are *not* able to separate the oxygen from carbonic acid." p. 184.

manure alone, which was applied at the same time on the surrounding land.

The same valuable work contains a caution to the farmer which may save him from a dangerous error. "He is not to suppose that calcareous earth can enrich a soil by direct means. It destroys the worst foe of productiveness, [acidity] and uses to the greatest advantage the fertilizing powers of other manures; but of itself it gives no fertility to soils, nor furnishes the least food to growing plants." In other words, it is the strong box for the treasure, but not the treasure itself.

Lime also possesses the property of making sandy soils closer and firmer, and clayey soils lighter. It is a mean between two extremes.

I was conversing several years ago, with a farmer from a sandstone district, who expressed some surprise that 40 bushels of wheat could be raised to the acre. "I don't believe," said he. "that our land could be made rich enough to produce such a crop—it would lodge." I am entirely of the same opinion, unless lime be employed. Stable manure is too stimulating—the stem grows too rapidly—it is succulent and weak. Whether the lime by combining with silica assists in stiffening the stalk, or not, we may be certain at least, that it yields nourishment as the plant needs it; and that every part will be healthy and properly developed.

Professor Emmons says in one of his Geological Reports, that the most fertile soil formed artificially, by the mixture of different earths, yielded on analysis 37 per cent. of carbonate of lime. As it is known, however, that lime in some soils soon ceases to be a carbonate,* it is probable that the real quantity of lime was even greater than what was indicated by the analysis. I have seen soils of remarkable fertility, that naturally contained a very large proportion of lime; and there is no danger of having too much when it is properly applied.

In drought, how are plants supplied with water? After a shower, the soil may be wet enough for a time; but when the sun and wind dry the surface, the moisture rises up from below by capillary attraction, as the melted tallow rises up through the wick of a candle to supply the deficiency above. It is from this circumstance that our crops over deep beds of sand suffer less in dry weather than where the subsoil is hard and impermeable—showing the benefit of deep and thorough ploughing. In either case, however, as the supply begins to fail, and the soil grows drier, its finest parts absorb moisture from the air; and the plants are constantly nourished by this invisible fountain.

But the different constituent parts of the soil act with different degrees of energy.† Of the earths, the silicious is the weakest,‡ and the aluminous the strongest, while lime holds an intermediate position. Not one of these however would do by itself. We want sand, because no soil consisting entirely of impalpable matters is fertile;* and we want it to keep the soil loose, so that the air can enter its pores, and give up the water which it holds as vapor.—Without such assistance, stiff clay or aluminous earth would absorb but little moisture from the atmosphere, because it cakes, and shuts out the air. Lime is also a valuable auxiliary in rendering the soil more absorbent, independent of its other indispensable qualities.

But the soil, however it may be tempered and constituted, can never be absorbent in a high degree without culture. Some crops indeed require more of this quality than others. Thus Indian corn requires more than wheat; and wheat more than the grasses of the meadow. But vegetable and animal matters are more absorbent than the earths; and culture only can properly introduce them into the soil. Even when there, frequent stirring is necessary to keep the ground loose and the pores open, for the free admission of the air and the easy passage of the roots.

Our coats sometimes become spotted with mud. We apply the brush, but the bristles pass over without effecting its removal. What is the reason? The clay which was suspended in the water, forms a glaze or crust. It is just so with the interior of a soil which has laid long unstirred. The clay forms a crust round the inside of all the little cavities, preventing the free circulation of air, and the introduction of moist vapor. The fertilizing principles are excluded.

The celebrated Tull, observing the extraordinary effects of high culture, concluded that plants fed on mellow earth, and Duhamel adopted the same notion. Their philosophy was *coarse*, but their practice was *fine*. If we were to follow their example, making plenty of fine earth for the plants—not to *feed on*, but to *drink from*, our crops might be greatly increased. One of the chief errors of our husbandry is to cultivate too much land, because it is only half done. Half the quantity with double the work on it, and double crops would be found more profitable.

I have long believed, however, that no part of the system required reformation more than our management of manures. Manure has been called the wealth of the farmer. When it is taken out in the spring, it is commonly scattered over the ground in large lumps; the plough comes along and covers them, or not, as the case may be. If covered, they intercept the ascent of the moisture from below, especially in dry seasons. If not covered, they lie wasting on the ground—of very little value. Indeed some excellent farmers have satisfied themselves that strawy manure is unprofitable for summer crops.

I am far from holding that opinion, however. The error consists in not applying it to the soil in the best manner. In the spring of 1840, I had no ground for field beets, but a small lot where corn had grown for two years in succession. It was unfit for such a crop without manure; and I had only fresh manure from the stable, which has long been considered most unfavorable to the beet. My necessity, however, prevailed against opinion; and I took the responsibility. From each line where the beets

* Agr. Chem.

were to grow, two furrows were turned so as to leave a wide dead furrow. Into this the manure was thrown from the wagon, each forkful touching the one just behind it, till the row was completed. It was well covered by turning two furrows together over it, which *held it down* while the harrow was passing four times in succession, breaking, pulverizing, and mixing it intimately with the soil. Again two furrows were turned together over the row, and the harrow passed twice more—in all, six times. By this process the ground was reduced to a fine tilth; and if there were any better beets in the county, I did not see them.

To me, it was a most instructive experiment. I have often seen manure applied to corn fields, but never in any case where it was so completely incorporated with fine earth. Even in the driest part of that season, the ground was always moist and mellow.

I am satisfied that we have been too saving of our harrows. Thirty years ago, there was a method of ploughing in this country called '*cut and cover.*" It was ploughing, not to the *shares*, but the *halves*—the furrow slice covering the space where a furrow ought to have been. I am apprehensive that our ideas of harrowing were learned in the same school. When grain is sown, is it not the prevailing opinion that it is harrowed enough when the seed is covered? I had a narrow land harrowed sixteen times in one day, and was satisfied that the labor was well applied.

For beets, or corn, or potatoes, what would be the effect of ploughing in a heavy dressing of stable manure, harrowing twice, and repeating the operations of the ploughing and harrowing four times more, adding each time to the depth of the soil? I have not yet performed the experiment, but the nearer I have approached it the finer has been the crop. Thorough culture would seem to require that every little lump should be broken, so that the roots could wander freely in every direction, and that every drop, of a summer shower, should be caught and retained for future use. Hard land and thin soils have some resemblance to a dish bottom upwards.

An instrument for pulverizing the soil was invented a few years ago in Virginia, by Thomas B. Gay. It is called the drag-roller, for it operates just as a roller would that does not *turn*, but *drag*. Take a hollow log, six or seven feet long, split it in two, and one half would serve for this instrument. The greater the diameter, the easier it would run; and be less liable to clog by gathering clods before it. Three feet would be better than two, though either would answer. Frame two pieces of scantling into it, connecting them in front; and to this fixture the team is to be attached.

Do you believe that clods as big as a man's fist, or as big as his head, are more useful to the crop than stones of the same size? I do not. But if we can break them—grind them to dust—and leave them on the land, they would do as much good as other mellow earth of the same bulk. Now in warring against the clods, this instrument is formidable; and most so before they become thoroughly dried. On the same day therefore that the plough turns them *up*, let the drag-roller grind them *down*; and let me suggest that lumps of barn yard manure would escape not much better.

Stable manure, however, is often saved for the wheat field; and at any time during the summer, either before or after harvest, it is taken out and thrown into heaps, where it lies wasting until seed time. It is then thrown round into large lumps as before mentioned, the plough covering some, while others too big to cover stick up over the field. If the wheat is harrowed, perhaps some of these pyramids are upset or demolished; but often the harrow serves them as the plough did—gives them a shove and passes on. Now it seems very clear to me that manure applied in this way is comparatively of little value.

There is another class of farmers who manage things differently. Soon after the warm weather commences in spring, they collect all the manure of the barn yard into large heaps; and work it over, two or three times in the course of the summer, so that the straw may moulder and be more easily mixed with the soil. This advantage—the only one that I can discover, is indeed secured, but at a heavy expense. The best part of the manure passes off to visit their neighbors, or roam at large through the atmosphere, leaving the worst part, though still of some value, for the owners. The praise of industry is theirs, and the reward of working for nothing and finding themselves.

Another set of farmers, more interprising still, make up all their barn yard manure into compost. This is done by successive layers of manure, rich earth, and lime, together with any refuse stuff, animal or vegetable, that may be at hand—to be turned and mixed several times in the course of the season. Such manure is always valuable; but with a little more knowledge, its value might be much increased.

Let us consider this subject. From a heap of fermenting manure, a vapor continually rises, very different from the exhalation of a pond, as our noses might testify. Perhaps some may think that such thin diet as that would be of no consequence to a plant; but I can assure them it is the best part of the manure. Humphry Davy filled a three-pint vessel with a bent neck, from a fermenting heap of stable manure while it was hot, and turned the beak among the roots of some grass. Nothing but vapor left the vessel; yet in less than a week the grass grew with much more luxuriance than the grass in any other part of the garden.*

The value of this vapor is therefore evident; but how shall we save it? In the first place, the fermentation should be very gradual. Make the heap in the shade, or on the north side of a building, and manage it just as you would manage a coal-kiln. The more the air is excluded the slower and better will be the process. Now covering it with earth will have this effect; but vapor will rise even when it ferments slowly, and therefore marl may be freely scattered through the heap as it is made; but no quick-lime. Lime, indeed, should form an outside covering for the whole pile (when marl is not at hand); but it should be carefully prevented from coming in contact with stable manure, or any

* Davy's Agricultural Chemistry.

animal matter. It must not touch them. It spoils them. A layer of earth should be interposed ; and then the lime would be highly useful in catching and retaining the fertilizing vapor as it rises.

I believe there is no difference of opinion on this subject among chemists. Humphry Davy speaks in the plainest language against mixing quick-lime with common dung as injurious ; and other eminent men fully accord with the doctrine. On the outside of the heap, however, quick-lime in a few weeks would be carbonated ; and after undergoing this change, it might be safely mixed with the compost. A fresh coat may then be applied.

But some farmers may not wish to apply their barn yard manure in the spring, or make it into compost—they may prefer using it after harvest, and yet not have it wasting in the mean time. In that case I would advise that it be thrown inward where it lies thin, just so far that this work conjointly with the work of covering it, shall amount to the least labor. Then cover the whole with straw or earth to protect it from the sun ; and cause it to be trodden down by the cattle as firmly as possible to exclude the air, and prevent fermentation. Some of you may recollect when forking up such matters after harvest, that the straw in spots was bright and unchanged. That was where it was well trodden. All change is attended with loss ; but as some change may be expected strew lime or marl and plaster plentifully over it, to absorb, or arrest the fertilizing vapor.

The effect of plaster (composed of lime and sulphuric acid) has long been a source of wonder ; for it was a wonder how one bushel could add more than 20 times its own weight to a crop of clover. Inquiring minds of course have been busy in trying to explain the mystery ; but I doubt if all the properties of this manure are understood even at this day. Humphry Davy was inclined to think that plaster was a necessary part of the woody fibre of some plants, analogous to the bony matter in animal structures. The plant could not do without it, though it wanted but little ; and hence so small a quantity had such a powerful effect. " Plants which seem most benefited by its application," says that eminent chemist, " always afford it on analysis."

When this theory was announced some thirty years ago, it was rejected in this country, where the effects of plaster were much better known than in England, but if he could have shown that it enters into such plants in any definite proportion, some of the arguments against him might have been refuted. It appears, however, that he never pursued the inquiry with much interest.

Judge Peters of Pennsylvania had done more than any other person to extend the knowledge of this manure, and to favor its introduction. He had been very diligent and minute in his inquiries ; and though not a professed chemist, became satisfied that sulphuric acid was the active ingredient in plaster. He showed, from the observations of Berard, that lands near Catanea in Sicily, abounding in volcanic matter, including sulphur,* were very fertile ; and from an experiment by the same person, that brimstone, pounded, sifted and mixed with ashes, had a surprising effect on lucerne and clover. Sulphuric acid greatly diluted with water, had a similar effect.

As a further confirmation of the effects of sulphur or sulphuric acid, when Chancellor Livingston was travelling in Flanders he saw the farmers preparing pyrites for manure. This mineral is a combination of sulphur and iron, and when partially burnt is employed in the same manner, and for the same purpose as we use plaster. Dr. Chapman of Pennsylvania found a similar result from sulphuret of barytes.

Last summer, a new work called, Organic Chemistry, by Professor Liebig of Germany, was first published in this country ; and it has been considered by those best qualified to judge, as constituting a new era in agriculture. It is not my intention, however, to detain you with any of its details, except his explanation of the effect of plaster on growing plants.

Ammonia is an essential part of the food of plants. It affords all vegetables, without exception, with the nitrogen that enters into their composition. It is very volatile ; but sulphuric acid (furnished by the plaster) can prevent its flight, and fix it in the soil. This can only be done, however, when the plaster is dissolved. The sulphuric acid then unites with the ammonia, and the carbonic acid of the ammonia unites with the lime.

Such is the purport of Professor Liebig's explanation of this great mystery. If he is correct in ascribing all* the effect of plaster to this new combination, its importance in the economy of our farms must be evident. All our fields, pastures and meadows, ought to be strewed with it ; and in accordance with his suggestion, it ought to be scattered in all our stables, and over all our barn yards. The quantity required is not great ; and many experiments may be instituted at a trifling expense.

I ought to say, however, that this theory appears insufficient for explaining all the phenomena, in connexion with the use of plaster. Why is its effect on clover so extraordinary, and on wheat so insignificant? Judge Peters, after using it forty years, said he never found it beneficial on winter grain ; and others, after long trials, thought it did little for the natural grasses. All these, however, are powerfully affected by stable manure—by the very ammonia† which that manure yields. And what do we observe? Clover of luxuriant growth, and close along side of it, wheat without any indication of benefit received, though both have been plastered alike.

Again—Professor Liebig informs us that every shower of rain, or fall of snow, brings down ammonia to the ground where the plaster ought to arrest it, and the plants that feed on it ought to be more thrifty ; but we have much testimony to

* A late traveller writing from Italy, says of the peasants residing in the neighborhood of Vesuvius—" If their houses are burned, they return, when the lava cools, to build new ones, and cultivate *a soil inexhaustibly fertile.*"

* " The evident influence of gypsum upon the growth of grasses depends only upon its fixing in the soil the ammonia of the atmosphere."—Liebig, p. 142.

† "Animal manure acts only by the formation of ammonia."—Liebig, p. 136.

show that on many fields no trace of such improvement could be discovered. These facts may not be inexplicable; but they appear to me at present, quite sufficient to hang a doubt on.

I am aware that we have statements in regard to the use of plaster, of the most conflicting kinds, so that with some few exceptions what one denies, another affirms; but would this be so if it acts solely in the manner described by Professor Liebig? A simple cause might be expected to produce a uniform effect. For instance: poudrette is a simple cause; and as far as I have understood, it operates with uniform effect, whether on clover, wheat or cabbages.

On some soils, indeed, plaster is uniformly inefficient—not the trace of any effect is perceptible. This inertness has been more frequently observed in the *tertiary formation* near the sea coast; and therefore it was ascribed to the salt vapors. Plaster, however, succeeds well in many places on the coast, and fails in others far beyond the sea breeze, so that the cause seems to reside in the soil, and not in the air.

There are several substances that decompose plaster, besides the cabonate of ammonia. Carbonates of potash and soda have the same power. In the hands of the chemist, plaster and common salt readily change into sulphate of soda, and chloride of lime; and Judge Peters said, "I ruined a bushel of plaster by a handful of salt—it was unfit for either cement or manure." Some of the oxalates also effect its decomposition.

When this happens, the plaster no longer exists: and most of these results are not known to be of much value as manures. Such failures, however, rarely occur on calcareous soils, or on such as contain a due proportion of lime. There plaster generally proves beneficial; and even in England it has succeeded on such lands. Many years ago, in the south-eastern part of Pennsylvania, some farmers thought it would supersede the use of lime; but it gradually lost its effect; regaining it, however, when the land was limed. Wherever plaster proves of no use, therefore, try liming. On a small scale, it may be done at a trifling expense; and may lead to the most beneficial results.

And remember that plaster must be dissolved before it can do any good. Sometimes there is not rain enough for this purpose in summer, and therefore, there is always a risk to sow it late in the spring. Let it be done early.

I have now arrived at my last paragraph. From bogs or deep swamps manure may be manufactured to a great extent. Three parts of peat and one of stable dung are mixed together, and fermented through the summer. It was used in England* many years ago; and has been found in New England, equal to the same bulk of stable manure, and more permanent in its effects. †

CASKS FOR PRESERVING GRAIN.

From the Farmers' Cabinet.

Mr. Editor—On a late visit to a branch of the Cooper family, New Jersey, I observed that the granary, or place for stowing away grain of different descriptions, was fitted up with bins in the shape of very large and strong iron-bound casks of the usual shape; and in these, the wheat, &c., was preserved for any period, no matter how long, without fear of weevil, grain-worm, or any other species of vermin, or damp and mouldiness; the grain being introduced by means of a funnel through the bung-hole, which, when the cask is full, is very carefully closed and made air-tight, the hoops being driven occasionally to cause them to become so. Now by this very simple arrangement, the whole crop of grain on a farm may be preserved for years, as perfectly free from dampness or disease of any kind, as though it had been kiln-dried; the convenience of stowage being as great as in open bins; the casks standing on low tressels or sleepers, admitting a bushel measure under, they can be rolled on to the bung; or the grain might be drawn off by a large tap made for the purpose.

HISTORY OF THE CANE.

From the South Western Farmer.

We promised in a late number a history of the seeding and growth of the cane, which a few years ago was found in such abundance in nearly every part of this country.

At the first settlement of our state all the richer lands were found covered with a growth of this singular plant, so dense that travelling through it ten miles a day, with severe labor, was quite as much as could be done, and the only way to get an extension of vision further round than ten or twelve paces, was to mount a tree or some other eminence higher than the tops of the cane. The size and height of the cane varied with the quality of the land. On thin land it was found not thicker than one's little finger, and not higher than 4 or 5 feet. Increasing in size as the land was better, it was occasionally seen from two to three inches in diameter, and attaining the height of 30 or 40 feet. Until the year 1830 a considerable portion of the present corporation of Vicksburg was one of the thickest and heaviest kind of cane brakes, and all the uncultivated parts of that most fertile region of the world perhaps—the hills which strike the Mississippi just above Vicksburg at old Fort McHenry, and continue to skirt its shores as far as our boundary line extends, were clothed throughout with the perennial verdure of the cane's most graceful foliage. During that year nearly all the cane of this range of hills, and we believe of the interior on this side the Mississippi, blossomed, seeded and perished. The seeding did not extend to Louisiana, unless in a few small spots, nor did it extend to much of the river bottom on either side; and there were occasional clumps which did not seed until the following year, together with some that did not seed at all; though such were soon destroyed by stock.

The ripening of the vast quantities of seed during the summer of that year (1830) presented in those parts of the country where the cane was abundant, scenes of overflowing plenty, unequalled in any other land than one of fable. The grain was about the size of a grain of rye, and be-

* Davy's Agricultural Chemistry.
† Jackson's Geological Report on Rhode Island.

gan to ripen towards the latter part of July. Each cane sending out a head of seed at the extremity of every leaf branch would yield perhaps a quart, and so heavy as frequently to bend the cane entirely to the ground. Cattle, hogs, birds, squirrels, and every thing which fed on it, became seal fat, and reveled until winter in the midst of the wasteful gencrosity of nature.

After ripening its seed, the cane withered and died entirely, though it did not fall to any great extent till the following year. It was then thoroughly matted over the whole surface of the earth, forming a layer of 6 inches or a foot of dry and combustible matter.

Those who have never witnessed that most sublime spectacle—a field of dead cane on fire—can form no idea of the scenes then frequent among us. A prairie on fire has often been the theme of description. But the terrific magnificence of the conflagration of a cane-brake we think unequalled. The fire may be known at the distance of 6 or 8 miles by a roaring like the coming of a hurricane, and a thick column of black smoke which rolls up in the horizon over the spot of the conflagration. Nearer to the scene, and yet not in sight, the incessant reports, caused by the explosion of the heated air in the joints of the cane, brings to the mind nothing more forcibly than the idea of embattled armies engaged by myriads in the work of death—while the giant monarchs of the forest, consumed at their roots by the devouring elements, occasionally tumble with a crash which jars the hills like the mingling of heavy artillery in the battle. Coming nearer, the scene which meets the eye makes the brain reel. A tumultuous ocean of flame seems rolling over the hills, leaving nothing but smoking ruin behind its thundering march. For a while perhaps the flame moves on evenly and regularly. Presently it is lashed to fury by the breeze and leaps ahead in long tongues of flame with the speed of a courser. Again as it sweeps up the ascent of a hill and gains the top, it will seem to leap away from the earth and try to seize the sky itself in its embrace. Occasionally as it meets a bunch of cane standing erect, or seizes on the dry bark of some tree it will be seen wreathing itself in columns forty or fifty feet in height and playing among the topmost limbs of the forest—making altogether, with the deafening noise—the vaulting flame—the dense clouds of black smoke—and the cinders which fall in showers behind it—one of the most sublime exhibitions of the power of the great element, fire, which we ever beheld.

After such a conflagration has passed over the land, as may be supposed, not a green thing is seen. The ground is left clean and mellow, with a fine dressing of ashes, and nearly every tree completely deadened. Cutting the cane and burning it off in this way, is the universal method of clearing in the cane regions; and the process leaves the ground in so fine a state that superior crops of corn are sometimes raised with no other labor than to stick holes with a stick where the corn is to be planted—covering with the foot and afterwards knocking down the *mutton* cane which will spring up from the old roots.

The manner of the growth of cane from the seed is peculiar. In the fall which followed the general seeding in 1830, the ground became covered with the young plants from the seed which had fallen and been neglected by the hogs. They came up fine and tender, very much resembling nimble-will grass; and stock grazed it with great eagerness. It continued green through the winter though it did not grow; and where the land was not burnt off as we have described above, and the stock was not plentiful enough to extirpate it, the cane again took possession of the soil. The peculiarity of its growth is in this: no stalk grows, no matter how long it may stand, more than it grows the first season it sprouts. It shoots up to its full size in a few weeks, and there remains till it dies. The roots however continue growing from year to year until they reach perfection, and as all the stalks after the first year shoot from the joints of the roots, so as they advance in growth, they send up every year larger and larger stalks until at last the *mutton* cane is seen to sprout up as large as a man's wrist and attain the full height and perfection of the plant. It is many years—some 8 or 10—before the roots attain their full growth and send up the full sized cane. The first year, from the seed, the plant does not grow higher than six inches—there it stands and grows no more. The next year suckers spring up from the roots of this first plant about the size of a goose quill and about 18 inches high—there *they* stand and grow no more. The following year still larger suckers spring up; and so on until the large mutton cane are sent up—which shoot forth to full size and height in a few weeks, and these stand until seed time again rolls round, and they bear their fruit and perish. Asparagus is the only other plant with which we are acquainted which has a similar growth.

We have heard a great many pronounce as to the length of the periods at which cane will seed. Some say, it will spring up, attain its growth and seed in 7 years—others that it will only seed every 14 years. Our own opinion is that both periods are too short, and that at least 20 years will elapse before the plants from the seed will in their turn produce. The cane from the seed of 1830 has not yet after 12 years attained the full size of its predecessors, in those parts of the country where it has been left unmolested; and we have never heard our oldest citizens speak of witnessing but one general seeding—that of 1830. Partial seeding however may be seen in nearly every cane break much oftener. A few clumps—sometimes several acres will run to seed, die and fall. These are no doubt bunches which did not seed with the balance and run their course out of the general order. A few dwarf cane too—about the height of a man's waist—may be frequently seen seeding in the midst of the larger growth. The exemption of most of the bottoms, on this and the other side of the Mississippi, from the general seeding of 1830 may be accounted for from the fact that overflows kill cane—and that which stood at that time in these bottoms was not probably of the same age as that on the hills. The overflow of '28 killed large bodies of cane and on lands habitually overflowed cane will not grow. On much of the ground where the cane was killed in '28 it has again sprung up from seed which either had laid dormant in the soil, or had been floated and deposited there by the water from other sections. As late as '35, when we were last to to any extent through the swamps of the Mis-

sissippi, the cane on land where it had been killed in '28 had not yet attained any thing like full size, even though it had been exempt from subsequent overflow; and the difference in the size of the cane was an unerring index by which to judge of such lands as the overflow of '28 had left uninjured.

The first feeling on contemplating the history of this singular though common plant is surprise that none of our planters have taken the pains of securing the seed and laying down pastures in cane. We take great pains to secure clover and other grasses of precarious growth among us, and have neglected this indigenous, hardy and perennial plant which we will venture to assert will sustain more stock to a given amount of ground than any grass we can cultivate. It is equally valuable at all seasons of the year. In spring and summer the young *mutton* cane, as they are called, which spring up as tender as asparagus and as quick, furnish a sweet and nutritious food which sheep, cattle, hogs and horses seek and devour with eagerness. And in winter, when nearly every thing else has disappeared, the cane continuing green furnishes a plentiful if not a very rich supply. Cane that is grazed from will not grow up to the usual height, but the plants as they sprout will cease growing where they are bitten off, and bunching out, form what is called switch cane, being the best for pasturing, as the higher growth is beyond reach. Most of our medium lands would grow cane, which, to follow the dictates of nature, should be sowed in the fall after the land is broken up perfectly loose.

Those acquainted with any section of the country where the cane is seeding, will doubtless confer a favor on the public by making it known, so as to enable those wishing seed to procure it.

THE FARM AND FARMING OF THE REV. J. H. TURNER.—NO. V.

Remarks on lime as manure. (a.)

For the Farmers' Register.

In one of my late communications I incidentally adverted to lime, and its use as an improver of the soil, and promised to resume the subject at some future time. This promise I now propose to redeem. And this I do rather with the view of *seeking* instruction than of imparting it. In fact, I enter on this subject with very great diffidence. What I have thus far written has been the result, for the most part, of my own experience and observation. Thus supported, I felt myself warranted in speaking in terms of confidence. But when *lime* becomes the subject of inquiry, I candidly confess my want of information, and give notice beforehand that I must rely more than I wish upon that too fruitful source of argument called *theory*.

It is true that I have made *some* use of lime, and on more than one occasion; and it is equally true, that I was most sadly mortified and disappointed in the expected results. Two of my near neighbors, A. Robinson jr. and F. Staples, esqs., as I before intimated, both used lime with no better success. But in all these cases, the quantity used was too small, and the experiments made too few, to warrant any thing like a general conclusion. I am not therefore prepared, with my few and imperfect experiments, to resist the immense mass of evidence which may be adduced on the other side of this question.

A few years ago I enjoyed the pleasure of passing through the luxuriant part of Pennsylvania embracing the rich counties of York and Lancaster. Almost every field I saw indicated the highest degree of improvement. The clover, the wheat, the corn exhibited a dark luxuriant hue, which plainly told the great fertility of the soil. I inquired into the cause of the beautiful scene which was every where spread before me, and in all instances received the same answer—the mighty agent was *lime*, which had converted that whole country into a lovely garden spot.

In addition to this, the editor tells us of the great and salutary changes which have taken place in Prince George, in Charles City, in James City, and in several other counties in eastern Virginia, all resulting from the same cause. Then we have the testimony of Dr. Braxton of King William, and of the Messrs. Wickham of Hanover, and of many other judicious farmers in other portions of our state, all tending to substantiate the same general result. With this overwhelming mass of evidence before me, I cannot withhold my assent, that lime is in some form or other a most excellent improver.

It is also worthy of remark, that wherever lime exists in a natural state, a foundation is at once laid for improvement to almost unlimited extent. It is this that has made the country around Lexington, in Kentucky, the lovely spot that it is. The hand of skill and industry is the only thing needed to convert the whole valley of Virginia into one lovely garden spot. Indeed, where the foundation is a lime-stone, *skill* may be in a great measure dispensed with; the chief things necessary are industry and patient perseverance. (*b.*)

But there are many other sections of country in which this important ingredient does not exist in a natural state. Here too is an almost endless variety of soils, differing from one another in nearly every essential quality. Some are silicious, others argillacious, and others again mixtures of both in various degrees. Some have a clay foundation, others a hard pan foundation, and others again are so unfortunate as to have no foundation at all. Now, it cannot be conceived that the same material which is profitable to one must necessarily be profitable to all. We cannot admit the Thomsonian principle, that the medicine which causes one disease, will also cure its opposite. Hence results the absolute necessity of that skill which grows out of a long course of close observation and careful experiment. And hence we may account for the fact, that in the use of lime, so many mistakes have been made, and so many disappointments have ensued. (*c.*)

Nor ought it to be forgotten, that this article, which is so useful in some circumstances, is positively injurious in others. It either cures or kills the patient. We can never administer it on the principle, that if it does no good, it will do no harm. Lime is in its very nature so caustic and active, that it will always act either for good or for evil. It is therefore an exceedingly dangerous article in the hands of the injudicious and

inexperienced. As intimated in a former number, the writer, with others, has already been injured by it. Hence the great necessity of a close and intimate acquaintance with this whole matter, before we tamper with an article so dangerous. (*d.*) As a mortified and disappointed farmer, then, I do hereby call on those who are now reaping the rich harvest of their successful enterprises, to come forward and tell me and the public the whole secret of their success. And as I have reason to fear that the farmers will do on this, as they have done on many similar occasions, put off the thing from time to time, until it will never be done, I do in my own name, and in the name of many others, call particularly on the editor to take this matter in hand once more, and to give us the result of his long and intimate acquaintance with this subject. In common with many others, I hereby record my great and lasting obligations for what the editor has already done; but he will allow me to say, that his previous communications have dealt too much in mere *generals*. Being intimate with the subject himself, he has fallen into the error, too common among writers, of supposing that his readers also had some acquaintance with the subject. Whereas many, if not most of us, are still profoundly ignorant, and thus venturing in the dark, have sustained considerable injury. What we seek for then is not *generals*, but *particulars*. And that the editor may be at no loss to know on what points we wish to be informed, I will here state a few of them. We wish particularly to know,

1st. What kind of land lime specially benefits. Whether silicious, or argillacious, or a loam? (*e.*)

2d. What kind of a sub-soil it ought to have. Whether a red or white clay, or hard pan? (*f.*)

3d. What proportion is proper to the acre on each kind.

4th. In what state it ought to be applied. Whether caustic or mild? (*g.*)

5th. What is the most suitable time to make the application.

6th. On which can most reliance be placed, on stone-lime, on shells, or on marl?

7th. Ought the applicatien to be made as a top-dressing, or immediately covered?

8th. What crops are most benefited by it, and what crop ought immediately to follow the application?

9th. At what intervals ought the process to be repeated? (*h.*)

10th. Is it ever safe to apply it to poor naked land? (*i.*)

I have stated these queries just as they occurred to my own mind, without any reference to order, and I should be very thankful for a minute answer to each of them.

Having now professed my ignorance of this whole subject, it may seem strange to say, that I have any theory at all about it. But the fact is, I have experimented a little, and, with the aid of observation, reading and thought, have ventured to form my own theory; and, as it differs somewhat from any I have seen, I will frankly detail it.

According to the best information I have been able to obtain, the use of lime as an improver has been of recent date. Virgil, in his Georgics, and other Roman writers on agriculture, as far as I recollect, make no mention of it in this respect. About forty years ago, Sir Humphry Davy established his experimental farm in England. Previous to this but little wheat was raised in that country. Their supplies were derived, for the most part, from other portions of the world. Indeed, the opinion was very general that wheat could not be raised advantageously in that country. In this state of things, Sir Humphry, among his other experiments, after applying lime to his particular soil, succeeded in raising fine crops of this grain; from which he drew the general conclusion that lime was the great desideratum, and that the soil of England would produce wheat when supplied with this article. With this high authority before them, the farmers of that country generally resorted to the use of lime, and, whether it is owing to this cause, or to other sources of improvement, the fact is, that England has become one of the best wheat growing countries, so that it now produces a large proportion of its needful supplies. (*j.*) But it is worthy of remark, that the ardor which once prevailed on this subject seems now, in a great measure, to have subsided. We constantly hear much said about other and newer manures, but we hear but little said about lime. From this I conclude, that lime with them has pretty well had its day—the whole energies of this enterprising people being now directed to other materials, which are probably destined in their time to be superseded by something newer, and therefore still better. (*k.*)

How long lime has been used in *this* country, and *where* its use commenced, I frankly confess my ignorance; but, if I am not greatly mistaken, its general use in Virginia commenced *after* the publication of the editor's 'Essay on Calcareous Manures.' And here, without intending any compliment to Mr. Ruffin, I consider it but sheer justice to say, that to him we are indebted for most, if not all, the benefits which have resulted from the use of this article. After expressing myself as above, it may seem strange that I should wish to impose on him still more trouble. It is simply because I like what he has written so well, that I wish him to write more, in which new effort I hope he will not deal with us as having taken our diploma in this art, but will condescend to treat us as A B C scholars.

There is, however, one term frequently occurring in the above treatise, and often repeated in almost every subsequent treatise, to which, if I understand it aright, I must offer my unqualified protest. The term alluded to is, that lime is specially useful in *fixing* the manures in the soil. The old theory was, that lime was not an enricher, but acted as a stimulant, powerfully urging vegetation to seek and to appropriate to itself all the nutriment that might be in its reach. This theory seems to be now very generally exploded, and in lieu of it, we are told that its special use is in *fixing* the manures in the soil. Now what is the meaning of this word *fixing?* Are we to understand by it, as it seems naturally to import, that, by applications of lime, manures are made more permanent and durable, and thus actually last longer? (*l.*) If this be the meaning, the editor and I, and all others who understand the thing in this way, must join issue. For what is lime? And here, without attempting a chemical analysis of this substance, it will answer my present purpose

to say that, in its very nature, it is a strong caustic alkali, the natural and direct tendency of which is to reduce to their original elements all the substances, both animal and vegetable, to which it is applied. Lime, for instance, finds substances in a solid or liquid state. It changes them from this into the aeriform state, and then they pass off in the form of their various gases. Hence its great efficacy as a cleanser of stercoraries, and other offensive collections of decaying matter. The ammonia is speedily driven off, and the residuum is left in a sweet and harmless state. If then this be the direct tendency of lime, it seems to me to be the very last thing to make manures more permanent. Instead of *fixing* them in the soil, it decomposes them, and the gases being set at liberty, will make their escape.

Now whilst stating the above, I readily admit that applications of lime to coarse unfermented manures, may be of very great service. (*m.*) Manures in this state decompose very slowly. It is also of very great service to lands filled with turf and other vegetable matter, in an inert state. Such manures commonly decompose very slowly. If they evolve their gases at all, they do it so slowly as to furnish very little nutriment to growing vegetation. Hence it is that no judicious farmer expects much *immediate* benefit from applications of coarse materials from his farm-pen, or from dry straw or dry litter from the woods. It is now pretty well ascertained, that it is the *gases*, and the gases alone, which nourish our crops, and that these are evolved only during actual decomposition. Now, with manures of this kind, lime must be very useful. It hastens a process which would otherwise be slow, and the crop being already on the land, takes up the gases as they are set at liberty, and thus receives benefit. It is in this way that I account for the fact that in the few applications of lime I have made, one was successful, the others were mortifying failures. The successful application was on land newly cleared, covered with litter, and filled with small fibrous roots. Here the lime had vegetable matter to act upon, and the growing crop derived the benefit from the rapid decomposition, which the lime caused it to undergo. In the other instances, the land was naked, or nearly so, and the lime having nothing to act upon, no gases were evolved, and consequently no food was furnished to the crop; and as might naturally be expected, the whole affair, expenses, labor and all, terminated in a "splendid failure." I would not therefore hesitate to recommend considerable applications of lime to forests to be speedily cleared, or even to old fields pretty thickly covered with young pines, which it is intended to reclaim. Then I would leave the brush and other litter, for at least one year; after which, I should expect to bring the land into successful cultivation, not by *fixing* these materials in the soil, but by subjecting them to a rapid decomposition, and thus (if I may be allowed the expression,) *unfixing* them.

But perhaps the editor and other writers who are fond of this term *fixing*, may mean something else. They may mean that lime, where manure or other vegetable matter already exists in some form, does, by rapidly decomposing the same, saturate the soil with fertilizing gases, and thus impart a vigor which will enable it to throw up a strong crop of vegetation, which, falling and decaying on the land, will not only keep it in good heart, but actually improve it. In this way the original manure has not been fixed or made permanent, but it has imparted to the land a vigor and fertility which enabled it to cover itself with a strong crop of vegetation, and this, in its turn, decaying on the land, makes that fertility permanent. If this be the meaning, I give it my hearty concurrence; and thus it falls in with my theory on which I slightly touched in one of my former numbers. But then it ought to be borne in mind, that lime does not make the manure *permanent;* it merely hastens that process by which the manure is changed from an inactive to an active state, and then a permanency of fertility is insured by successive crops of vigorous vegetation. Instead, therefore, of the lime *fixing* the manure, the manure is fixed by means of successive crops of vegetation, which constantly rising up and then decaying on the land, make fertility permanent. It is these constant additions and accumulations of manure which can by any possibility fix or make them lasting. The idea therefore I wish to convey is simply this, that no applications of lime on a previous manuring can so fix that manure as to render subsequent manurings unnecessary. On the other hand, if the crops be removed and no equivalent be returned, the land will constantly decline, so that, instead of *fixing* the manure in the soil, we shall fix something there which we will find infinitely worse. (*n.*)

Or perhaps the meaning of this term may be that lime is specially useful in neutralizing or destroying that principle in *acid* lands, which seems to render applications of manure to such lands almost useless. Now I pretend not to say what that principle is. It may be acidity itself, or it may be something else which always abounds in acid lands. But be it what it may, there is something in such lands, as every observant farmer well knows, which seems to dissipate and scatter to the four winds his manure, almost as fast as he applies it. The whole fertilizing effects of the manure seem to be exhausted upon one single crop, so that the land is almost as poor at the end of the year as it was at the beginning. I have some such land, and I have often wished it was in the moon, or any where else out of my sight. It cost me just as much as the best land I own, and I hereby offer to *give* it to any one who will take it away, so that it may never harass my sight or purse any more. (*o.*)

Some persons are of the opinion that manure *sinks* in such land. But I cannot think this correct, for, on examination, I find that if it have any foundation at all, it is a hard pan so obdurate that it can scarcely be penetrated, even with the pickaxe. This being the case, I cannot admit the idea that the manure *sinks*. I rather incline to the opinion that the manure is dissipated, and thus rises up and goes off, not in the form of ammonia, but of some other gases which do not nourish vegetation. But be this as it may, a question of much more importance is, how is this evil to be remedied? Can this malady be cured by lime? Or is it to be ranked with cancer, consumption, and other incurable diseases which afflict the human body?

But we often meet with acid lands, which are not imbedded on a hard-pan substratum. Most

of our high-lands, where pine is the prevailing growth, are of this description. Here the soil is generally of a light silicious character; and here lime, judiciously applied, I doubt not, is very beneficial in rendering the manures permanent. The great desideratum here is something to neutralize the acid, and as it is well known, that alkalics will have this effect, lime, next to manure, must be the "one thing needful."

One word as to the discussion which has been going on for a short time between Mr. Nicol and myself. The editor, in the last number of the Register, calls it a "*controversy*," and seems to intimate that it has been carried on with unkind feelings. Now to this term, and to this insinuation, so far as I am concerned, I enter my solemn protest. I never entertained one unkind feeling towards Mr. Nicol; and judging from what appears in his "rejoinder," I would think that his feelings are as kind and respectful towards me. The truth is, that when I wrote my piece, I mistook my man. His communication was dated "Sandy Point," and from his frequent reference to the same place, I naturally supposed that he was the proprietor of that great estate. As such I prepared a dish into which I threw some salt. * * * * * * * * In fact, I made it a pretty pungent affair. But then this mess was not intended for Mr. Nicol. * * * Had I known or even suspected that Mr. Nicol was the worthy manager and not the proprietor of that great estate, my bill of fare, if I had furnished any at all, would have been of a very different order. I now not only know who Mr. Nicol is, but have had the pleasure of seeing him at the late meeting of our Agricultural Society. I was exceedingly busy on that day, so much so that I could only give him a cordial shake of the hand, intending to intimate that I had no unkind feeling towards him, and if he had any towards me, I verily believe that I *shook* it out of him. So that we are now better friends than we ever were before.

But I must say one word to the editor. He says, he has pruned both of us. How much he pruned Mr. Nicol, I cannot tell; but he has pruned me so close as to leave almost nothing but the stump. Finding, as he supposed, too much salt and other seasoning in my dish, he undertook to take it out, and in so doing, he will allow me to say, he has pretty nearly verified the old saying, that "too many cooks spoil the broth." If therefore he will allow me to "shoot no more bolts," he will in his turn be very careful as to the criticisms which he admits on my anonymous essays. I feel just as tenderly for my brats *without* a name as *with* a name.

J. H. Turner.

Notes by the Editor.

(*a.*) It has never been our usage, nor inclination, to exercise the almost universally assumed editorial privilege of replying to opponents in advance of the publication of the pieces so answered; nor even to answer by appended notes, as will be done here, and has been done in a few former cases when, like this, it was manifestly more convenient and better for the clear understanding of both sides to take that course. In the present case, the manner of the call made upon us, and our respect for the source from which it proceeds, both forbid us to neglect it, and pass it by silently. And yet, if it were attempted to answer the call fully, and in a separate and substantive article, it would be necessary to quote and repeat the many questions, and state at length the many objections or difficulties to be replied to, so that the reply could not be otherwise than very voluminous and tedious. Therefore, to save time and words, we shall take the liberty of appending in notes, at the end of the communication, the particular answers or remarks that may seem necessary—and will refer to other accessible sources for the more full information which may still be wanting, notwithstanding these notes.

The ground of discussion now presented by our correspondent is altogether different from what we had asked for and expected. We had requested (at page 154,) a statement of the particulars of his own applications of lime, which had totally failed of effect, (really or apparently;) and we had hoped to be able to find out from such statement of particulars, and to point out, the causes of the failures. But instead of our being permitted to pursue that course, and perhaps to occupy something of *new* ground on this subject, Mr. Turner has gone more upon theoretical views than practical matters, and has required many answers and reasons which had been (as we had supposed) already presented by us at sufficient length, and with sufficient clearness, in previous publications—and which, if repeated here, would be a long and wearisome task. For one question put to him, he has answered by asking twenty more. In some respects, if not all, to which the foregoing observations may apply, our esteemed correspondent must pardon us for expressing the doubt whether the fault which causes the necessity of further explanation to him of our views be not more in his own slight attention heretofore given, rather than of our want of fulness and explicitness in former statements. However, be that as it may, we desire above all things to be as plain and as clear and intelligible as possible in all writings upon agriculture; and we will bear in mind these our friend's difficulties and objections, as well as any others known, and endeavor to remove some of them, hereafter, by using still greater care in preparing the next edition of the essay to which he has referred in such kind and gratifying terms of general commendation. The publication of such an edition, en-

larged and increased in value no less than in bulk by the addition of more recent lights and later experience, is designed to be commenced some time within this year; and in the appropriate parts, whether of reasoning or of statements of practice, the alleged existing defects of sufficient fulness or particularity will be had regard to, and supplied when deemed requisite. Referring then to the last edition of the "Essay on Calcareous Manures," or, when that is really deficient, to the next forthcoming, for whatever may he here omitted, we will proceed to give such answers on particular points as may appear necessary.

(*b.*) In the preceding paragraphs, the writer seems to have withdrawn his previous denial (as we understood it) of the general benefit of and general necessity for calcareous manures on soils; and to become their eulogist in as general and as strong terms as we should be disposed to use. But still we would desire to bring back the discussion to the ground on which it was raised, viz.: the particular facts of the failure of Mr. Turner and some of his neighbors (in some or most cases of trial) to obtain any benefit from liming. We were before sure that Mr. Turner did not entertain the slightest doubt of the facts of success alleged by the several individuals to whose practice he has now particularly referred; and we are just as far from doubting his failures, or the occurrence of such facts in his practice as served to form his belief of his applications being failures. But the business is not to defer to authority, no matter how good, but to try to reconcile these apparently opposing facts and results, by presenting all the circumstances of both modes of trial. This we have aimed to do, in former publications, and at great length, as to *our* results, both successful and unsuccessful, and will add any deficient particulars that may be hereafter required. In regard to the opposite results of Mr. Turner, the circumstances are stated so slightly and so generally, that it may be presumptuous for us even to pretend to judge of the causes of their failure; but nevertheless such causes as seem probably to have operated, and such reasons as seem to apply, will be mentioned.

We understand from the former concise and general statement and present repetition of Mr. Turner, merely that he (and two of his neighbors also) applied lime to soils almost naked and barren, and found no effect or benefit whatever therefrom. Now, though we believe that there was a great mistake as to there being *no effect* ultimately produced, still we would freely admit, (and it would be precisely what we would have anticipated and predicted of such an application, and such circumstances,) that there would be no early and obvious improvement—perhaps not enough to be distinguishable, and certainly not enough to be profitable, without putrescent matters being also applied at the same time, or afterwards. The great and most beneficial operation of calcareous earth as manure is to combine chemically with putrescent manure, or any matters serving to feed plants, and thereby "*fix*" in the soil these otherwise fleeting and wasting matters. If there were no such enriching or alimentary matter in the soil, of course no such beneficial *fixing* action of lime could take place—and on an exceedingly barren soil, exhausted by tillage and close grazing to the lowest possible degree, this action might be so little as not to be perceptible. Nearly all our own practice and earlier cultivation have been on originally bad soils and very poor and exhausted lands; but excepting the numerous and extensive galls of the washed slopes and hill-sides, we had no experience of land so excessively poor as Mr. Turner described his to have been when he commenced operations, and when (as is presumed) he applied the lime. But even though no early benefit from applying marl or lime be *seen* when applied to naked galls, or to other almost as barren land, the application would give to such land the power of combining with, holding, and thereby receiving benefit from, putrescent manures (or any vegetable matter) afterwards to be applied. Now we presume (in the absence of any express statement) that this land so limed by Mr. Turner, without benefit as he supposed, has been since heavily and repeatedly dressed by putrescent manure, and, like his land generally, has been highly improved by such lavish manuring. Now suppose that the small quantity of lime before applied has actually and fully performed its office of *fixing* in the soil as much of the alimentary matter since given as it could combine with, this small effect, however valuable in proportion to its extent, would be lost and invisible, amidst the ten-fold greater quantity of putrescent matter applied every three years, and which was, as *we infer*, mostly wasted for want of lime to combine with. According to a previous statement of Mr. Turner's, (p. 151, 2,) he found his applications of putrescent manures, (much of it rich manure from town stables, 1250 bushels to the acre,) to show "an evident falling off in the second, and especially in the third and fourth crops [or years.] This madea second manuring necessary; and," he adds, "I am now convinced that excessively poor lands, such as mine were, cannot be made permanently rich under *three* distinct manur-

ings." For our part, we suspect that *thrice three* such manurings (of putrescent matter alone) will not be *permanent*, without lime applied in some manner (*and coal ashes* is one, though a feeble source of supply,) is given to the land also. Now, according to our view, if a sufficient dose of *mild* lime had been given *before* the first putrescent manuring, even although the benefit of the lime had not been distinguishable at first, nor appreciated since, it would have caused two of the manurings to be as serviceable as the three, up to this time, and much more in all future time. And if this view and opinion were admitted to be true to the fullest extent, still it will be manifest to the reader, inasmuch as such effects are merely *preservative*, and where other far more immediate and active manures are lavishly applied afterwards, and repeated in rapid succession, that the effects really due to the lime might not be known and appreciated, or if seen at all, would be ascribed to other causes. Especially would this be the case, when the true action of lime in soil was not understood, or such benefits from it are expected as are produced by putrescent and alimentary manures.

But in our own practice, the "fixing" and preservative power of lime was had in view, and such effects looked for; and such as was our own poor and bad land, (and poor and bad enough it was,) we have never made an application of marl thereon that was not both effective and profitable; nor even on a naked gall, which was not effective in improving it, by fixing other and alimentary manures, (if such were added in any manner,) though perhaps such improvement of galls might sometimes cost more than the land was worth after the highest improvement thereof.

We do not, however, pretend to set forth our own limited experience of results, in a particular locality, as indicating precisely such as are to be expected in other localities, where other and unknown conditions of soil may exist. And we are ready to admit, in advance, that there is existing a difference of circumstances, of which the causes are unknown to us, in soils above and below the granite range, or falls of the rivers, though of like texture and general appearance. And we have inferred, as different effects of this unknown difference of causes, that gypsum is more generally active and useful on lands above the falls than below; and lime and calcareous manures generally more effective and profitable below the falls than on lands of similar appearance above. On this interesting question, many facts and proofs are wanting. And, to gather all the light desired, the advocates of either of these manures, generally, should not insist that their rule of action, however good for themselves, is of universal application; but should also examine for, and give all due weight to, the real or apparent exceptions to be found elsewhere. We freely acknowledge that we are much in the dark on this as on many other particular points of this general and extensive subject for investigation.

But Mr. Turner admits the propriety, and probable profit, of liming his land, *after* he has or shall have applied three successive heavy dressings of putrescent manures, at intervals of three years each. But it would have been far better to have applied the lime before. The full comparison of our views and statements would bring us both nearly to one point of agreement in this respect. The only remaining difference seems to be, that, while we recommend making ready and applying the *preserver* before exposing to waste and loss the thing desired to be preserved, Mr. Turner's opinion and designed practice would reverse the order, and furnish the means for preservation 3 to 9 years after the putrescent manure had been applied, and during all which time, by his own showing, it had been rapidly wasting. The putrescent manure he most correctly regards as his great treasure. The calcareous matter in soil, or to be applied to soils, where not existing, is the *lock* on that treasure. Is it then most judicious and economical, to furnish the lock *before* there is yet any treasure to secure, or to wait until after it has been for years in a state of daily extraction and waste?

(c.) It is very far from being the fact, that the same prescription of lime for soil is made for opposite diseases. The disease is *one*, though there may be some variation of minor symptoms according to difference of the constitution and previous treatment of the patient—and that disease is the great deficiency of lime, without which in sufficient quantity no soil can be good. In charging upon these soils the cause of their worthlessness, the allegation must be of what is *absent*, and not what is *present*. We had the misfortune, within the last few hours, to be compelled to hear the speech of a very windy and magniloquent member of the bar, who in referring to the baseness of an individual whose case and character were in question, said that "he was brim-full, to overflowing, with the total want of all moral rectitude." Now all these bad lands, however various and numerous their vices and defects, are all "brim-full, and to overflowing, with the (almost) total want of" *lime*. Therefore, the disease, or the foundation of the complication

of diseases, being one and the same, there is no quackery in prescribing one remedy as essential for all.

(*d.*) In the "Essay on Calcareous Manures," the author particularly, as well as *generally*, stated that the carbonate of lime, or *mild* lime, (as presented in marl,) was what he had almost exclusively operated with, and to the operation of which his theory and rules applied. *Caustic* or quick-lime was particularly excepted, though a particular consideration was given to that important exception, (See Essay on Calcareous Manures, 2d edition, pages 32 to 35.) The *only* condition of soil for which we there recommended *caustic* lime, or even thought its use allowable, was that of newly cleared or fresh land, full of vegetable matter; and it was in precisely such a case that Mr. Turner found decided benefit and profit from the application. In all other cases, (and we would not insist even on that one exception being requisite,) we would prefer to have the lime *carbonated* or rendered mild, by exposure and absorbing and recombining with carbonic acid. This end will be sufficiently secured by the mode of application introduced by the late Fielding Lewis, and which was described in no. 1, vol. i., Farmers' Register, and is in general use on the lower James river, wherever lime is applied. Any other mode of sufficient exposure to the atmosphere, that would reach the same end, would as fully guard against all the danger feared from the *causticity* of lime. And wherever such evils have been suffered, we must be permitted to say that they have not only *not* been attributable to our published instructions and advice, or the want of stating exceptions, but in direct opposition to both our general views and particular statements. If all the persons who suppose they have suffered injury from the too general opinions or incorrect instructions in the 'Essay on Calcareous Manures,' were examined as to the grounds of their charges, we suspect that it would appear that nineteen in twenty of them had not so much as read the work.

(*e.*) Liming, (in the sense stated in the last note,) operates more quickly and fully (for the first crop,) on silicious or sandy, than on clayey and stiff soils; but beneficially and profitably on all grades of texture of soil, if deficient in lime, as a natural constituent.

(*f.*) We care nothing about the subsoil, provided it be not *wet*, which bad quality is indeed an effectual bar to improvement by lime, as well as by every other known manure. We had some little red and more of white clay sub-soil; but most of ours was barren yellow sand sub-soil, generally deemed the worst of all; and on land having this very base sub-soil, our improvements by marl have been the most striking and most profitable. This is the kind of sub-soil, we infer, that Mr. Turner speaks of as of land having "no foundation at all." We would desire no better foundation for improvement by calcareous manures.

(*g.*) In giving the following particular answers as required, to particular questions, we must repeat, and beg that it may be borne in mind, that we have almost no personal experience of *caustic* lime as manure, and do not approve its use, unless in some very few cases; and, except when especially and expressly referring to *caustic* lime, that our remarks will here apply, as heretofore, to the *carbonate of lime*, whether as presented naturally in marl, or by burnt lime, after becoming mild by exposure.

(*h.*) Some portion of the questions, from 3d to 9th inclusive, have been already answered in the preceding remarks, and all of them susceptible of being precisely answered, as we conceive, in the report of Fielding Lewis' farming (above referred to,) and in the 'Essay on Calcareous Manures.' And to answer fully here, would require 20 more pages of addition to these notes. In regard to burnt lime, (though that always becomes very soon carbonated in the usual practice of exposure, and before the first crop begins to grow,) some more full and valuable information is also presented in a preceding article, respecting the liming on Brandon, (page 279.) As it respects the *kind* of lime, provided it be but rendered mild, we should care very little as to what source it was derived from. Whether found in marl, or new or mild burnt lime, and whether from stone or shells, the only important consideration is, of which kind can a dollar's worth of labor and money furnish to the land the greatest number of pounds of *carbonate of lime*.

(*i.*) It is always "*safe* to apply it to poor naked land"—if it be *mild* lime, and not in excessive quantity for the circumstances of the land.

(*j.*) We would by no means concur in the several opinions and statements expressed in the preceding parts of this paragraph; but it is unnecessary to object to them, as they do not affect our positions. It is enough that we agree with our correspondent in his last stated position, that lime has generally been used in Britain, (where needed and accessible, we would add,) and that the greatly improved production of that country "is due to this cause, or to other sources of improvement." We would only desire to substitute the word *and* for the "or" above—giving to lime

the credit of a large part, but only a part, of the great agricultural improvement of England, and still more of Scotland.

(*k.*) We might well afford to concur in the opinion expressed, that lime in England "has had its day," but in a different sense from what is above intended. Lime *has* "had its day," indeed; that is, it has performed all its proper service, wherever it has been fully and sufficiently applied to give the needed change of constitution to the soil, and still to leave enough excess of lime to combine with and fix any early expected additional supplies of putrescent manures or other alimentary matter. In this sense, marl also "has had its day" on some farms we know of in Virginia, and the use there has been discontinued for some years. But it was only discontinued because all the surface had been fully marled; and other manures have been since sought to be applied, in preference, and almost exclusively, because these manures, vegetable and animal, are now highly profitable. Still the benefits at first derived from the marl continue and increase with every year. No advocate for the use of calcareous manures, who knew any thing of their true operation, has recommended their continued repetition—or their being substituted for putrescent, or for all other manures. In our own case, we have not only almost ceased to supply marl (for the above reason,) but have become as ardent as is Mr. Turner for applying putrescent manures on the lands where the marl "has had its day," and where, before marling, the application of putrescent manures was almost labor and expense thrown away.

(*l.*) Precisely—such is the *effect* of what we have termed the power of calcareous earth of "fixing" putrescent manures—and the mode of that operation, we maintain, is that the calcareous earth forms a chemical combination with both the soil and the putrescent manure, and thus retains the manure, and makes it permanent, until and except so far as the superior power of growing plants shall withdraw the putrescent manure for their sustenance from that combination. As we have never ascribed this power to the causticity of quick-lime, nor advocated lime while in a caustic state for this operation, all Mr. Turner's objections to caustic lime on this score might be admitted, without affecting in the least our position in regard to the "fixing" property of mild lime.

(*m.*) *We should* object to the mixing of caustic lime with even the coarsest of manures, if they had any rich and very putrescent matter intermixed—for to such matter the contact of caustic lime is always injurious, in the manner which Mr. Turner has correctly stated.

(*n.*) Having before stated what we meant by the term and the operation of the "fixing" of manure, by calcareous earth, it is not necessary to say any thing farther in regard to any mistaken inferences of our meaning. One small exception however it may not be improper to express, which is to state that we certainly *did not* mean to maintain the position, which Mr. Turner here opposes, that any "applications of lime on a previous manuring can so *fix* that manure as to render subsequent manurings unnecessary." He who would assert such doctrine, and as founded on his own practical experience, would deserve no respect for any other opinions, either in reference to his judgment or his veracity. In the first case, lime, (meaning *mild* lime,) applied *on* a previous cover of putrescent manure, and which was of course passing off in more or less waste, could not possibly be thoroughly intermixed and combined with the manure, so as to stop the waste, or to retain as much as the *amount* of lime under more favorable circumstances might combine with. This effect would be much better produced by the lime having been made the *first* application even to "dead land," and so thoroughly incorporated with it, that the manure would meet lime every where. But even that would not serve, except so far as the quantities of the calcareous and the putrescent manures were in proportions suitable to combine with each other. If the lime given to an acre be sufficient to combine with and fix and save only 100 bushels of putrescent manure, and 1000 be put on, the 100 may be saved, but 900 will be lost as surely and as quickly as if no lime had been applied. But even that amount of putrescent manure, and its fertilizing action, which the lime in a soil *could* fix and retain under a lenient and judicious course of tillage and rotation, (whether it be equal to 100 or 1,000 bushels of stable manure to the acre,) certainly will, in time, be drawn from the soil by the crop, if under severe and continued tillage, and removal of all the growth. And so (though it may require a long time and much trouble) may the best natural soils, such as were limed by the hand of the Creator, be also exhausted and reduced to poverty. But even when so reduced, the fixing and recuperative power of the lime in such soils will be apparent, if any chance for recovery be allowed to the land; as it will improve rapidly, and get rich again, if but left to itself; whereas Mr. Turner's poor land, and ours, that were "born poor," would remain so for ever, if left to get rich merely by rest, and their own growth for manure. Therefore, the admission that a marled or limed soil, after being enriched, *may* be empoverished by scourging cultivation, is not a contradiction of our position of the *permanency* of the improvement made by calcareous manures, and also by putrescent manures

combined with them. It is enough for this position, that land so improved can bear any judicious and farmer-like system of cropping, in grain and grass, which gives a proper return to the soil, though taking off much more in frequent crops. Such, for example, is the Westover and Brandon four-shift rotations, of three crops of grain and one of clover in every four years; yet the land is kept *improving* under that heavy draught on its productive power, after liming, with only the manures of the farm, and gypsum. If Mr. Turner were to stop his heavy dressings from purchased manures, even after having made the land as rich as is possible without lime, how long would his land bear up, under such heavy exactions as those referred to, and retain all its previous and highest power of production?

(o.) As much as Mr. Turner would seem, in some parts of his remarks, to oppose our views in regard to lime *in the general*, he furnishes in *particular statements* the strongest confirmation of them. And here is a very remarkable case in point. There *is then some soil* that Mr. Turner's generous and even lavish and repeated triennial manurings *cannot make rich* temporarily, much less keep rich? If we were to say that the cause were wholly (as no doubt it is in part, as Mr. Turner supposes,) the acidity of such soil, (or something else,) which "seems to dissipate and scatter to the four winds his manure, almost as fast as he applies it," and lime would remove this evil, and let the manure act and remain as on other lands, it would be but presenting the "fixing" proposition in a different form. Without having seen or had any experience of any land so bad as he describes, and without entering upon the discussion of the *modus operandi*, we can venture to assert that "the something" and the whole matter with this soil, which causes such very uncommon bad qualities, *is the want of lime*. And so sure are we of this, that if we were residing in Mr. Turner's neighborhood, we would accept this land which he offers to give away, and think that we could show him that the making it calcareous would make it abundantly retentive of putrescent manure. Of course, we infer that the land so described and denounced is dry, and *has a soil*, however poor it may be. If land be wet, and remain undrained, improvement by lime, or any other means, is hopeless; and if the original soil has been washed away, or otherwise removed, though improvement would be quite feasible, it would be of more cost than profit. We presume however that Mr. Turner does not refer to any such extreme cases as these, any more than to surfaces of entire rock, or pebbles, or of blowing sand, where soil had never existed. As to all ordinary and naturally poor soils, and including the poorest of them, we entertain no doubt of their being universally susceptible of high improvement by lime; and that by using lime thereon judiciously, from one half to perhaps nine-tenths of the putrescent manures may be saved, which would be otherwise required to maintain any certain grade of increased productiveness.—Ed. Far. Reg.

REPORT TO THE STATE BOARD OF AGRICULTURE,

ON A PART OF NANSEMOND COUNTY.

Chuckatuck, May 16, 1842.

Mr. Edmund Ruffin, Corresponding Secretary of the Board of Agriculture of Virginia.—I received your communication (circular) only a few days ago, the letter having been addressed to me at Suffolk, and in compliance with the request, will answer such of the queries therein contained as come within my knowledge, though imperfectly.

My observations will be confined mostly to the land on Nansemond river and its tributaries, though they will suit the greater part of the county, except for the want of marl off the water courses, with which we abound on the banks of the river, with shell marl, or rotten oyster shells and decomposed vegetable matter, forming an almost black surface soil of 6 to 12 inches deep, the former settlements no doubt of Indians. Occasionally, on the river bank, and always on the creeks and coves, is found an abundance of marl, formed of clay and marine shells, both of which have been applied with good effect on our lands, when used with judgment; but owing to a want of knowledge of chemistry, and the caustic effects of calcareous matters, it was used so lavishly some years ago, as to render the land entirely unproductive, and will require many years to reclaim it, by rest and the use of vegetable matter, and the contents of the farm-yard. This injury is only partial, however. One field in this neighborhood was marled some eight or nine years ago, at the rate of 800 to 900 bushels per acre, the crops of which have never since paid one half the expense of cultivation; the land had been heavily cropped several years before, was worn down and naked; but in every instance, that I know of, where 100 to 150 bushels to the acre have been used, it has acted beneficially. It is difficult to overcome prejudices, and many will not use it, from the injury sustained by some by over-marling.

Most of our lands are what may be called level, and generally are so, except on the water courses there are some inequalities, produced by coves or guts running up into the fields.

The climate is vacillating, produced by our contiguity to the seaboard, generally feeling the influence of the sea breeze or easterly winds; indeed since my recollection it has changed very much, having later springs and earlier autumns, so much so as to render the cotton crop precarious, and causing the cultivation of it to be entirely abandoned.

Now, our crop is mainly corn, with peas, and oats, and potatoes, and melons, on or near the

water courses; some few cultivate wheat, though very few; but few sow grass seed, and then the preference is given to red clover, which is mostly grazed, very little cured for hay, so that our cattle have to subsist during winter on corn tops and husks, and by the spring are generally perfect Rosinantes.

The arable part of farms is generally small, 30 or 40 acres to 200, some few 300 to 400. Husbandry has been injured and retarded very much in this county, by the facilities afforded for speedily converting our labor into money, by lumber and the products of the river realizing more from an effective force, (men.) than the slow returns of agriculture on worn lands, few being able to employ such force in clearing or improving their farms. Still there has been some improvement in management by husbanding manure, by penning the cattle, and littering the pens, which is applied in the spring on the corn ground mostly in the hill, or on the sweet potato and melon crops, by those living on or near the water courses.

I may say there is no uniform system, if any system at all, in regard to the rotation of crops. The arable land is generally divided into two fields, often only one; one is cultivated always in corn, or corn and peas, the other sometimes in oats; though many are prejudiced against oats, thinking they impoverish the soil more than corn, and with such, the field lies idle or grazed until the next year, when it is planted in corn. But few have three fields, and no one more; so that you may judge the improvement is slow, if any; the greater part arises from the decay of the pea vines and the weeds and grasses, which grow after the suspension of the cultivation of the corn crop. The ploughing is generally shallow, to suit the surface soil, 3 to 4 inches deep, sometimes 5 or 6 on better or improved lands.

The land is always broken up with the plough, (Freeborn's cast-iron generally,) then checked off 4 feet square, or 5 by 3, and cultivated with the old fluke hoe plough, or three hoe harrow, commonly called the Eastern Shore harrow, as it was introduced here from thence; which keeps the land level and saves much hand labor. But few ridge, and cultivate one way only, though that system has a few advocates, and I am decidedly one of them. Some few use the double-shovel plough, which is a most effective implement, the best perhaps we have, both in execution and saving of labor, from the time the corn comes up until it is laid by.

The corn blades are always stripped from the stalks, and then the tops are cut, cured and stacked; the corn is gathered from the stalk and housed, as no small grain is to succeed it that fall.

The product per acre is about 15 bushels of corn and 10 to 15 of oats; in some instances more, often below.

Our fences are made of pine rails, crooked or worm fences as they are called, except in a few instances they are wattled or bushed, on a bank thrown up by digging a ditch; cedar boughs are generally used, driving in the banks stakes about one and a half or two feet apart, to weave in the branches, and makes, when care is taken, a very pretty and substantial fence.

Our teams are mostly horses, sometimes a mule or two, and rarely oxen; no horses are raised for sale and but few for farm supplies; calves and lambs are commonly sold in the Norfolk market, and pay better than raising beeves and mutton.

Most of our people are opposed to book farming, and of course to innovations on the old system, and denounce much of what they hear of in agricultural periodicals as humbugs, and hence arises, in a great measure, the low ebb of agriculture among us.

Nearly all the improvements made hereabouts are by those who have been readers of the American Farmer, the Farmers' Register, and the Cultivator.

I regret that I have not been able to give more interest in my reply to the queries submitted by the Board of Agriculture; my occupation is not wholly agricultural, my age too advanced, and travel too circumscribed, to give information entirely correct; if it should be worth nothing, you will of course throw it aside, or glean such parts as your judgment may prompt.

We have no agricultural society in the county, to our shame; there was one in Chuckatuck for a short time three years ago, but so little interest was taken, and but by a few, that it was given up.

I am pleased at the establishment of a Board of Agriculture, and think it calculated to do much good. Respectfully, WILLIAM SHEPERD.

REMARKS ON MR. TURNER'S THEORY ON ROTATIONS.

To the Editor of the Farmers' Register.

Big Lick, Roanoke, June 13th, 1842.

* * * Whilst I have my pen in hand, and am fresh from your Register, I will scribble what has been suggested to me by one of the pieces, which you can use your pleasure in throwing aside or publishing.

In the number to which I allude, the last, you publish the views of J. H. Turner, on rotation, without comment. Are your readers to construe silence into approval? We look to you as a guide, to conduct us along the safest path, when we are perplexed by the discordant and contradictory theories of distinguished agriculturists; and surely if there ever was an occasion when your counsel and warning were required, it was when you gave currency to the views of Mr. Turner. This gentleman, from his successful farming, his zeal for the agricultural interest, and his well written communications, has acquired a distinction which gives more than ordinary weight and influence to his opinions. Of course many, in a spirit of blind confidence, will embrace as the sound and irrefragable results of experience, whatever this practical farmer may advance, however opposed to the lights of science; unless you accompany the publication with your dissent from the errors and fallacies, in which he has involved himself, and into which he is likely, by his specious reasoning, to seduce many of his brethren.

What do you think of the leading idea of his communication, No. 4, "that a rotation of crops is unnecessary?" Is it not opposed to every opinion on this subject ever advanced by yourself? Is it not at war with every principle established by the experiments in vegetable

physiology? Is it not directly in the teeth of all that is taught us by Sir H. Davy, Chaptal, De Candolle, Liebig, Buel, and every other agricultural writer of reputation? And lastly, is it not opposed to the experience of every farmer who does not live within the smoke of a city, where the fertility of his lots may be almost maintained by the continual presence of an atmosphere loaded with gases generated by the filth of a crowded population?

It is a common observation of farmers in this quarter, that when lands are worn down with long continued and severe cropping, so that their yield in *grain* is not worth the labor of cultivation, they will produce a luxuriant crop of *clover*. Not less common is the observation, that old tobacco lots, when they grow tired of the crop which they have borne for a long succession of years, and refuse to produce the same heavily, however well cultivated or highly manured, can only be restored as a tobacco lot by a rotation. It would be easy to illustrate these opinions by many striking examples around me; but I deem it unnecessary to cumber this letter with them, as I presume there are palpable illustrations of their truth in every neighborhood in the state.

We have always thought that these results were perfectly natural, and consistent with the organic laws of vegetable physiology. We have been content with the theory, that some plants require a peculiar species of food, whilst others require a different. That, of course, when the peculiar food of the cultivated plant was exhausted, it was no longer capable of producing it, whilst its adaptation to the growth of other plants, demanding a different *pabulum*, was unaffected. We have always believed, too, that the excrementitious matters, thrown off by plants, were as incapable of nourishing plants of the same kind, as the excretions of animals are of being assimilated by the same species. We have believed, too, that the analogy is farther maintained in this, that these excretions may nourish other plants, differently constituted, as the excretions of one species of animals affords nourishment to another. Such have been the opinions of all enlightened agriculturists for a great many years: certainly ever since the theory was revived and illustrated by the genius of De Candolle. Liebig, in his great work on agricultural chemistry, maintains it, with some slight modification, in all essential particulars. He thinks that the excrementitious matters suffer various transformations in their passage through the organism of the plant, (pp. 54 and 55,) till at last, being capable of no further changes, they are separated from the system, by the organs destined for that purpose. That these exudations, though they may be absorbed, can never (until decomposed) be assimilated by the plants producing them, while they may very well be fed on by plants differently organized.

Independent of the cogent inferences from the known principles of vegetable physiology, in support of this theory, the experiments of Macaire Princep, alluded to by Liebig, seem to place its correctness above controversy. How will Mr. Turner, except upon the principles here advocated, explain the fact that plants of the *leguminosæ* family, wither in the water in which the same species have grown until the excretions have colored it brown, whilst corn plants grow vigorously in the liquid, and the brown color diminishes sensibly with the growth of the plant.

You will observe in this experiment, that the plants selected are unlike in their organism, and whilst the one feeds largely on the phosphates, the other requires scarcely any. I ask Mr. Turner if the inference is not irresistible, that the beans first grown in the water, had destroyed its fitness to sustain a second crop of them, either by exhausting the peculiar food on which they fed, or by *poisoning* the water with their excretions? It is not equally clear, that at the same time that the liquid was thus rendered unfit for the support of beans, it still retained a capacity for producing corn, and that this corn, instead of rejecting, actually fed upon the exudations of the beans? If true, as is proven, with regard to the *water*, I would again respectfully ask your intelligent correspondent, would it not be equally true of the *soil?* Can there be any difference, when every thing absorbed by a plant from the soil must necessarily be previously dissolved? I am sure he will at once admit that the second fact is a legitimate corollary from the first, and in so doing his own theory loses its foothold, and falls to the ground. If this experiment were not so perfectly conclusive, it would be very easy to pile proof upon proof, "Pelion upon Ossa," in support of it.

Liebig relates an instance of a landed proprietor in the vicinity of Göttingen, who, to obtain potash, planted his whole farm with wormwood. The consequence of which was, that it so effectually exhausted the potash in the soil, that it was incapable of bearing grass for many years—the grass requiring a large supply of the silicate of potash.

In combating these universally received opinions, Mr. Turner sets out, rather ominously, in the midst of a strange confusion of technical terms, and an entire misapprehension or misapplication of authors quoted, and when he has thus, under the delusion of an honest zeal for his theory, dove-tailed an ingenious and plausible argument, he then endeavors to varnish over the whole with some striking facts.

In adverting to this part of Mr. Turner's essay, I will not confine myself to his precise language where it is unimportant, as it would unnecessarily lengthen what I have to say, but merely quote the substance.

He says there is one ingredient which is necessary to all crops, and that ingredient is *fertility;* and that this ingredient is just as necessary to one crop as another. *Fertility*, as understood by him, is synonymous with humus, as understood by Prof. Webster, geine as called by Prof. Dana, and ammonia as maintained by Liebig. He makes, in confirmation, an extract from the second report on the agriculture of Massachusetts, whereof Prof. Dana says, "If we can induce the state of geine best fitted for each plant, then adieu to the doctrine of the necessity of a rotation of crops." Without quoting farther at present, let us halt and review the ground.

That this *fertility* here referred to, and easily comprehended by every farmer, is not, as Mr. Turner supposes, synonymous with humus, geine, &c., will be perfectly obvious when it is recollected that many plants, wheat for instance, will not

thrive in pure humus. The word fertility, as used by Mr. Turner, is much more comprehensive. Liebig states that, in many parts of Brazil, where the soil is particularly rich in humus, wheat will not thrive, and in many parts of Europe, where they have formed soils of mouldered wood, [pure humus,] it has been attended with the same result. The stalks attain no strength, and droop prematurely. The cause assigned is, that the strength of the stalk is due to silicate of potash, and that the grain requires phosphate of magnesia, neither of which substances a soil of humus can afford. Liebig adds that wheat will not flourish on a sandy soil or a pure calcareous soil, (*e. g.*, the bald, calcareous prairies of Alabama,) unless it be mixed with a considerable quantity of clay. These soils are deficient in the alkalies, which are indispensable constituents of wheat, while potash and soda are universally present in clay.

But Professor Dana says, "if we can induce the state of geine best fitted for each plant, then we may bid adieu to the doctrine of the necessity of a rotation of crops. This may be true, but the very condition on which it is made to depend destroys its applicability, as used by Mr. Turner. "*If we can induce the state of geine*," &c., is the language of the author. But how induce it? Geine or humus, or to be more specific, the decomposed organic matter of the soil can only be brought to the state necessary to give vigor to the growth of plants indiscriminately by the presence of alkalies. Humus is not soluble in any useful degree in water, requiring as it does two thousand five hundred parts of water for one of humus, while it is readily soluble in alkalies. If then you can always have the requisite supply of alkalies present, you at once induce that state of geine so much desired by Prof. Dana. But can any practical mode be devised of effecting this, other than a judicious rotation of crops, which will feed successively on the different constituents of the soil, and give to the great laboratory of nature time to restore what has been taken away?

But Mr. Turner, feeling probably the weakness of his argument, and the inconclusiveness of his authority, endeavors to sustain himself by a few isolated facts. It seems to me, however, that little weight should be given to these few straggling examples, ("*rari nantes in gurgite vasto*,") which his industry has picked up over our extended country, against the proofs of philosophical investigation, and the almost unanimous testimony of enlightened farmers in every quarter of the world. It is an old adage "that a single swallow does not make a summer," and my Lord Coke says, that exceptions to a general rule, instead of weakening, prove it. The most striking example relied upon by Mr. Turner is that recorded by Mr. Colman, the Massachusetts commissioner, who says, that he saw a rich alluvion field on the Connecticut river, the proprietor of which told him that without any manure it had continued to produce good crops of wheat for thirty years in succession. This you will observe is a piece of intervale land on the borders of a stream whose low grounds are of remarkable fertility, and whose inundations annually, or at intervals of several years, may have deposited new soil, and thus maintained its capacity to produce the same crop. The Nile, the Po of Italy, and many of the principal rivers of France, have long been employed as fertilizers of their low lands, and wherever they have been able to irrigate them, they exhibit the same capacity for production with the example cited by Mr. Colman. The most important alkalies always abound in such lands. The overflowing waters, too, hold oxygen in solution, and are thus enabled to act promptly and effectually in producing the putrefaction of the excrementitious matters contained in the soil. But, Mr. Editor, I did not take up my pen with the view of discussing this question with so skilful an antagonist as Mr. Turner, but merely to draw your attention to the subject, that you may enter the lists, and allow me to retire. This letter has insensibly grown to so inordinate a length, and so contrary to my intentions, that I feel that I almost owe you an apology for troubling you with it. When I had once embarked I found all my efforts to regain the shore fruitless, until the present moment.

Yours respectfully,

WM. M. PEYTON.

P. S. Allow me to add by way of postscript. In the same number of your Register, containing the article commented on, I observe, in a very sensible essay addressed to the Board of Agriculture, by Mr. Noel of Essex, an allusion to a universally conceded fact, which is in confirmation of what I have written, and of course in conflict with the theory of Mr. Turner, viz.: that a new peach orchard will not flourish on the site of an old one. He says, in his absence the holes which he had dug for an orchard were filled with the rich dirt taken from the sites of the decayed trees of an old one; and he seems to have viewed it as so palpable a blunder, that he goes out of his way to exculpate himself from any agency in it. I will here add, that I hope Mr. Turner will appreciate the frank spirit in which these strictures are made, when I add that I have read his agricultural essays with pleasure and profit, and that I hope he will continue to shed his light among his brethren.

W. M. P.

Editorial remarks.

We had supposed that, to so long continued and attentive a reader of the Farmers' Register as Mr. Peyton has been, it could not have been a matter of doubt whether our silence, or omitting to deny or object to the opinions of correspondents, implied assent and confirmation. We have had frequently to reply to the like question; and have always answered that our correspondents were free to present their opinions, however different from our own; and that we neither deemed it incumbent on us, or requisite, or even proper and justifiable, to offer editorial comments and objections to every opinion or statement in which we did not concur. If such had been our duty and usage, perhaps such comments and protests would have amounted in bulk to half the size of the articles commented on; and, after all, our opinions would have been worth no more than those which very many or all other observant agriculturists could as well form without our suggestions. It

was only when particular circumstances made it seem necessary and proper, that such editorial comments and objections were made—and then to no greater extent that was deemed requisite. But, independent of offering opinions thus particularly applied, there certainly has been no lack in the Farmers' Register of the expression of our own views, on every disputed and important question on which we supposed it in our power to throw light. And among such questions, there is scarcely one on which our opinions have been more frequently and decidedly given, than in favor of the propriety and necessity of changes and rotations of crops on proper principles. Therefore, as well as on the more general grounds above stated, it was not deemed necessary to reply editorially, to what we certainly deemed the "heterodox" doctrines of Mr. Turner, in opposito the necessity of changes in the succession of crops. Moreover, we had no doubt that some other would come forward, to oppose the views of Mr. Turner on this head, as Mr. Peyton has done, whose experience and ability would leave nothing to regret, because of our silence.

There was another reason for our being silent in this particular case. Mr. Turner came into the lists like a knight challenger of ancient times, slowly and sluggishly indeed as *Le Noir Faineant*, but also like him armed cap-a-pie, and seeming even to court the blows of opponents. His defiance was universal, and his ready lance seemed to threaten every quarter. Believing that he could not fail to arouse plenty of opponents on various grounds of contest, we were therefore the more willing to keep out of the *melée;* and more especially as being already engaged to oppose him upon one particular ground of controversy which could not be avoided, and in which we had endeavored to maintain our ground just before receiving Mr. Peyton's implied rebuke for our backwardness in the present question.

However, having been now thus called on to speak, we will add a few views on a different ground from that which Mr. Peyton has taken. He has occupied, and maintained well, (though we could not sustain him in every position,) the theoretical and scientific argument for rotations of crops. We will merely advert to a few detached facts, and matters of practice, without regard to theory, or to scientific reasoning.

Mr. Turner has quoted, as proof to sustain his opinions, the facts reported to him by several persons, that they had cultivated some one or other particular crop for several or many years in continued succession on the same ground, without deterioration of product, or only such deterioration as was caused by the decrease of fertility, caused by such exhausting tillage. The fact that any person had persevered in so injudicious a course for any length of time, and without learning his error from experience, would show him to be so injudicious a farmer as would alone bring his testimony into doubt. We are very sure that Mr. Turner will never have such proofs to offer from his own practice. But admit all the facts alleged by his informants of their success, and what do they amount to? Why, merely that, as in thousands of other cases, particular facts have contradicted, or have appeared to form exceptions to general rules. And if such apparent exceptions are to be admitted as serving to discredit general rules, then there is no one rule of good farming that cannot be so opposed, and its utility or necessity put down by the authority of facts. We have heard of cases as well established by testimony as those stated by Mr. Turner, which, if deemed conclusive, would as clearly prove that manuring land did no good to the crop—that purchasing and applying rich town manures brought the neighboring farmer to loss—that marling was injurious to land, &c. In short, there is scarcely any one agricultural opinion, however false and even ridiculous, that has not been sustained by one or more *facts* alleged by honest and veracious though certainly mistaken witnesses. And these particular exceptions referred to by Mr. Turner, however apparently successful and profitable, have never been considerable enough, or long enough continued, to cause any general practice to be founded on their example. No farmer, good or bad, has adopted, as a system of cultivation, the continuing the same crop on the same ground every year. There are many different rotations of crops pursued in Virginia, some few of which are good, or established on sound principles, and very many are decidedly bad and very objectionable. But, whether the rotation be right or wrong, every cultivator aims at some rotation, or change of crops, instead of continuing one alone in perpetual succession on the same ground. But universally as is rotation thus approved by practical cultivators, perhaps such testimony may be objected to, (as might many other general practices,) become of the ignorance of most practical cultivators, and the theoretical and visionary views of the more learned. Therefore, we are content to put aside all such authority, and to abide by the practice and experience of only one intelligent, observant, practical and successful farmer; and the credibility of that witness shall

be beyond all doubt or cavil—for we shall summon as that witness Mr. Turner himself.

If no change of crops be necessary, why does Mr. Turner follow corn by oats, and oats by grass? If there be no necessity for, or superior profit in this succession, why not as well reverse the order of these crops, or keep corn always on one field, oats on another, and grass on the remainder of the farm? If the answer be, that although corn might well follow corn, and oats follow oats, yet that the corn tillage cleans and prepares the ground for the growth of oats, and that the oats shelter the young herds-grass and clover, this explanation is, in fact, yielding the whole question, and stating good and sufficient reasons for the particular succession stated.

Mr. Turner's rotation is uncommon, and even peculiar. Still it is not therefore less a rotation; and, according to his peculiar position, we had given him credit for having adopted a rotation of very valuable features and effects. We especially admired the plan of two successive crops of corn, (though a different kind of hoed crop might have been better in place of one of them,) though such a repetition might have been a barbarous and abominable part of a course of crops at ten miles from a town, or where no putrescent manure could be obtained other than the farm furnished. With Mr. Turner, grass for hay is the most important and profitable market crop. Oats is the next in importance, and corn is not worth raising for sale, and only desirable for bread, and as a cleansing crop to prepare the fields successively for grass. To make the most of this cleansing operation, and because he can make up by purchased manure for the double exaction from the field, he cultivates two crops of corn in succession, and thereby makes the ground as clean as possible. Still herds-grass and clover would not take well immediately after corn; the shade of oats is required as shelter from the sun, and even the exhausting power of oats, to keep down weeds, and when reaped, to leave the land wholly to the young grass, when nursed to an age to be able to withstand both sun and weeds. The land then remains several years in grass, until weeds have gained the ascendency; when the crop and tillage of corn again are resorted to, for the purpose of recommencing the same rotation. We merely here present reasons, and aim to show that Mr. Turner not only uses a rotation, but one founded on sound principles, according to our views of the theory of rotation. The practice—the facts—the merit of the system—are all his own; and we have so much respect for his excellent practice, in this respect, that we are content to rely on it alone to rebut all his arguments against the necessity of rotations, even were his witnesses, and particular facts of exceptions to general rules, ten times as many and as cogent as they are.

Mr. Turner has been singularly unlucky in one case adduced as practical proof of there being no necessity for a change of crops. In this case Nature is the cultivator, and her farm "is the world, and the crops are the immense forests with which it is covered"—and Mr. Turner adds, "here too is no relief from rotation, for the same crop has been on the land for thousands of years." (p. 322.) Now the actual facts are directly the reverse—and so striking, that they have been often cited by writers as proofs of the necessity of changes of growth. The ordinary growth of a forest, even at the same time, is far from being the same crop. There are many different trees, as different in kind, and in their habits and wants, and products of manure by their decay, as the different kinds of cultivated grains and grasses. Therefore, even though the composition of a forest might appear to be unchanged in general, for thousands of years, yet it probably is the case that entire changes are perpetually made in the death and replacing of each tree. For example, a pine may occupy its place for a century, and then die, and be succeeded, not by another pine, but by an oak, which may stand for five centuries, and then be succeeded by a beech or poplar. But Nature is not satisfied with this gradual change and rotation by mixing crops. When fires, the depredations of insects, inundations, or tillage, have completely destroyed a forest growth, another succeeding growth is generally of trees entirely different. Thus, if a forest principally of oak, short-leaved pine, hickory, dogwood and chinquapin, in lower Virginia be cut down, and the land suffered to grow up again, (either early or late,) the next growth of trees will be almost exclusively of pine, and that of a different kind (the "old field pine,") from those which formed part of the previous cover. This is a fact notorious to every resident of this region. In other regions the changes of kind are different, but not less marked than these. And so complete have been such changes, and such totally new growths of trees produced, that many persons, and even some men of science, have thence believed in the spontaneous production of such new growth, or equivocal generation of the new trees, because they could not conceive whence their seeds had been derived. Such facts and proofs, directly opposed to Mr. Turner's position, are too numerous to be cited here. The subject is however curious and

interesting, and may be resumed hereafter in a distinct and substantive article.

In sundry of the particular positions assumed by Mr. Turner as proofs, or steps in his argument, we entirely concur, and suppose that no one would dispute. For example—it is not our opinion, nor the opinion of any reasonable advocate for rotation, that the mere growth of any crop serves to enrich the land producing it—or that any rotation of crops, if all are removed, can increase fertility. Nor would we dispute that some *tilled* crops, as corn, cotton and potatoes, (the very cases adduced by Mr. Turner,) may each be continued for many years on the same ground without very manifest deterioration, especially if dressed by various kinds of manures. But the true question is, could not, even in the most successful cases, these crops have been raised better, and to greater profit, if alternated with others? But even the admission of such exceptions cannot be made as to *broad-cast* crops, which are not cleaned by tillage. It is manifest and notorious, that neither wheat nor oats, nor any one kind of grass, can be continued to any profit, for years in succession on the same ground. Mr. Turner's statement of his own herds-grass giving place after a few years to green-sward, or to weeds, is not only a proof of this position, but also of Nature's urgent demand for a change of crops.—Ed. Far. Reg.

LIME.—THE WHEAT CROP, &c.

To the Editor of the Farmers' Register.

I lament, my dear sir, that you should think of giving up your useful labors; believe me when I assure you that the Farmers' Register has been a great public benefaction, and I must hope that you will not discontinue it. If you would be contented to take the vote of Virginia as your guide, I am sure you would have an overwhelming vote to go on. Men may differ, and do differ on every subject; from the hour that "darkness dwelt upon the face of the deep," man has dared to differ with his God, how then could you hope for agreement and sympathy? You have been his benefactor; what of that? Is he not in a free country, to take such things as he does, and his neighbor's grounds, and use them according to that barbarian thing called the "enclosing law," or "act of assembly." If a people be legislated into barbarity, why complain of them if they have not the fear of God upon their minds?

I owe much to your correspondents for amusement and instruction, and I would not on any account offend the least of them: let me, in this feeling, give you a few facts.

I have used, in the last twelve years, seventy thousand bushels of lime, with full and complete success. If I say the crops have been doubled, I am within the bounds of truth, save in two previous crops of wheat, which were failures. The present is very great, and I impute it to the difference in cultivation; the failures were after three and four ploughings, the present after one only. This however is the ninth day since I began my harvest, and I have not, from rain, cut twenty acres. A few days more of such weather must sprout it all in the field.

My corn is fine, and that for twelve years or more has been planted upon one ploughing; it is then coultered twice, and the cultivator finishes. But let me add that 8 cultivators pass over my field in four days, and I am persuaded that I get more from the atmosphere than the corn uses in its growth. For this reason I call it my chameleon crop, and feed it freely.

My oat crop upon limed land is not slow to show the power of lime. My clover, sir, is the food, the meat and drink of all other crops. I save my own seed, and sow in the pug, twenty bushels to the acre, as clean as the hand rake will make it from the thrashing machine, and that is as little as we give. This gives dear old Mother Earth a perfect robe of green; and when the blossoms set, it takes no poet's imagination to see that the dear old lady is in a dignified strut. I never fail to give one or one and a half bushels of plaster in March; and say what you may or please about philosophy, plaster upon limed land is worth six times its weight in fine flour upon your table. I forgot to say that I put a spoonful of plaster to each hill of corn as soon as it is planted, and that I plaster my meadows every spring with full and entire satisfaction as to results. Lime—lime—lime.

Fairfax county, June 18th, 1842.

THE WHEAT HARVEST

Has just been finished, or is about closing, on every farm in this region, and the result is certainly very far below the recent anticipations of an uncommonly abundant crop. Rust struck the crops, almost universally throughout eastern Virginia, but a few days before the wheat was fit for the scythe, which alone would have lessened the product very considerably. But added to the always disastrous effects of this worst disease of wheat, rains fell almost every day throughout harvest, and sometimes in immense quantity, so as to damage all other crops also, and especially the cultivated lands, by flooding and soaking the level, and washing the hilly surfaces. From Monday, the 13th, when the harvests here commenced, there were 10 or 11 rainy days, and only one day in which rain did not fall (Sunday, 19th); and during that time, nearly all the crops were reaped, and greatly exposed, and more or less damaged, or wasted by the necessarily hurried and bad work under such circumstances. Many of the shocks are yet wet, and require to be taken down for drying. No farmer can yet estimate his own loss, with any approach to accuracy, and of course a general estimate must be very uncertain. But the general loss cannot be less than one-fourth of the whole crop of eastern Virginia, as it promised a few days before ripening. We have passed through and seen crops of seven counties during harvest. No certain information from the mountain region has yet been received. The last rains were on the 25th, and since the weather has been fine. On the level lands of Gloucester, and still more of Mathews, great loss was counted on even in the oat crops, from excess of wet; and also to the corn crops, because of their foul state, and the long time before the ground could be again ploughed.—Ed. F. R.

June 29, 1842.

From the Dumfries Herald.

A NEW SOURCE OF THE BEST MANURE.

"Ne saturare fimo pingui pudeat sola; neve
Effetos cinerem immudnum jactare per agros."
VIRGIL.

In cold and temperate climates, the value of farm-yard manure has been known from the earliest period. It contains, or it leads to the formation of, every ingredient which our field crops demand from the soil, and it gives off its riches gradually as they are needed.

But it has always been a difficult matter to obtain this in quantity sufficient for the wants of a hard-cropped soil. The demands of our increasing population proclaim its inadequacy. The labor of cartage draws deeply on the farmer's funds; and the want of more portable manures is now extensively felt.

Bones, charcoal, burnt clay, and various salts, have, in turn, presented their claims. But of all the substitutes for farm manure yet proposed, none has claims so extensive and well founded as those of *wood ashes*. These already contain nearly all that plants draw from the soil. On warm soils, they so powerfully dispose the formation of ammonia and nitrates, that they render the addition of dung almost needless. They promote the disintegration of the soil, accelerate vegetation, and require little cartage.

The chief difficulty, as yet, has been the scarceness of the article: and my object at present is to point out the source of an abundant and cheap supply, for the wants of at least the present generation—*a supply which may be the means of adding to the wealth of Britain, doubling her produce, enriching her colonies, relieving her surplus population, extending her dominions, meliorating climate, and doing hurt to none.*

Our countrymen who emigrate to Upper Canada, find vast forests which they would more actively remove, if they had a remunerating price for their labor. By them, much of our pearl ash is supplied. They burn the wood, collect and lixiviate the ashes, evaporate the ley, and sell the "*black salts*" to purifiers, who present them to us in the form of pot or pearl ashes. Their methods at present are said to be clumsy, and their matters imperfectly collected; yet some of the more enterprising clear 20 acres annually, and pay all their expenses from the sale of their black salts. But, as many leave the ashes unheeded, where the wood is burnt, it seems that the supply is easily made to equal the present demand.

Now, sir, if a greatly increased demand were made, not perhaps for black salts, but for well burnt ashes, the labor and expense of lixiviation and purification would be spared, and an article better suited to the wants of the farmer would be obtained at a very moderate price.

It may safely be assumed that a ton of ashes is wasted for every hundred weight of good pearl ash which reaches this country. The increased carriage and freight would certainly be more than compensated by the want of trouble in purification, and hence we might have the ashes for 2s. to 2s. 6d. per cwt.

Eight hundred weight of these, per imperial acre, mixed in a little farm manure, would be quite enough for a five years' rotation. I have no doubt but that *six* hundred weight of these ashes, judiciously mixed, under cover, in six carts of good dung, will, in raising a turnip crop, be found equal to 30 bushels of bones, and will leave the ground as fertile. As every farmer can easily, on his own farm have more dung than he thus needs, his whole cash outlay for manure will be only 12s. to 15s. per imperial acre, instead of 90s. when he uses bones; and the difference of labor will be very trifling. On the second grass crop, the addition of other two-hundred weight of the ashes would *amply* pay the expense.

Let men of capital and scientific acquirements remove to Canada, and employ poor people in cutting and burning the wood, and clearing the ground. This will employ many who cannot now find work. The ground cleared, will require people to cultivate it. Roads will be improved. Our Canadian colony will rapidly grow in value and importance. An increased market for our exports will be opened; and the same trade may be extended to our other colonies, where wood abounds to a hurtful extent.

The guano trade must end in disappointment.

The bone trade sends the money of the British farmer to enrich the nations of Northern Europe; but the Canadian ash trade, will enable the Britons to put money out of one of their pockets into the other.

Nothing truly valuable is effected without some difficulty; and I merely throw out the suggestion, that better-informed minds may digest a working plan. The bulk of the ashes may be objected to, and some method of concentrating them may be devised. But while I know that trees contain too little silica for corn plants, I believe that the value of the ashes would be diminished at least one half, by the removal of silica.

We have lately heard of our government encouraging colonization. I hope their attention will early be directed to this matter; and I am, your obedient servant, P. G.

NEW ARTIFICIAL MANURE.

From the New Genesee Farmer.

We have seen, in several English publications, notices of a new manure invented by Mr. Daniell. The following account of it, given to the Royal Agricultural Society, we extract from the Boston Courier, a paper always alive to the subject of agricultural improvement, which quotes it from a London paper. We subjoin a letter on the same subject from our intelligent correspondent at Boston; and shall give, at the earliest opportunity, any farther information which we may obtain.

"It had long been a subject of inquiry, what is the food of plants, how are they supplied and what are the elements of their growth? There was every reason to believe that a reply could be now given of a more satisfactory nature than had ever been hitherto known; besides which, by the discovery of Mr. Daniell, a most important corroboration had been obtained of what had been considered the elements of vegetable growth; those elements were carbon or charcoal, hydrogen or inflammable gas, oxygen or vital air, and nitrogen. All these elements existed in the atmosphere, in combination with other elements, in which state they were found to be the sources of

vegetable developement. It was known to persons accustomed to rural pursuits that the heaps of vegetable substances collected for the purposes of manure, during the process of decomposition, became greatly reduced in bulk and weight. If they investigated the causes of this reduction they would find that it was occasioned by the evaporation of the carbonic acid and ammonia, the principal sources of nutriment to plants. The discovery of Mr. Daniell contained all the elements of vegetable growth. It did not supply new elements, but the same derived from other sources. It was known that by combustion substances were rapidly decomposed, and its operation produced the elements of vegetable growth. There were on the earth numerous plants which were apparently useless, but it was a principle in nature that nothing should be lost, and they were capable of a reduction into their elements, and being made the means of vegetable growth in other forms. The discovery of Mr. Daniell was suggested by the fact that, while burning vegetables, he observed that the ashes became blackened by the surrounding smoke, and when used in that state were very fertilizing. This led him to investigate the cause, and as the result of his investigation he had produced the new manure, the elements of which were carbon and ammonia. With it the principal properties would not fly off during decomposition, as that would take place in the earth. Among other advantages, it was light in weight, cheap, and capable of being produced in any quantity.

"This manure has been applied by the discoverer to his own crops, on three acres of poor land, in an elevated situation, on some of which he has grown wheat four successive years with improving results each year; its good effects are therefore founded upon experience, personal observation, and the testimony of other observers competent to judge. From the nature of the manure, it is applicable, with some variations in its composition, to every kind of crop. It is not a stimulating manure, in the ordinary sense of the word—that is, it will not have a tendency to call into activity the existing resources in the soil—but its direct effect is to convey to the soil the direct nutriment of future growth. This effect is produced by the supply of ammonia to the soil in substances calculated to retain it for a time—to again absorb it from the atmosphere—as they give it out to plants during their growth. It will probably prevent also the ravages of insects. Its mode of application may be various, according to the circumstances of the crops. The application by drill is conducive to economy of the manure, and a direct application to the infant plant as is the case with bone dust. Care, however, must be taken that it is not applied too directly to the plant, or without some portion of mould around it. This is the only precaution needed to avoid danger in its use. There is one required to prevent waste, as it is of a volatile character; that is, to place it several inches in the earth, as the earth will absorb and retain the volatile and valuable part. For grass lands, for similar reasons, it will be well to have it mixed with a considerable portion of ordinary unvalued mould. If the manure, as manufactured, be mixed with an equal bulk of mould, it will be perfectly safe for application; or if the mould of the field be stirred over it when drilled it will suffice. The quantity to be used will vary according to the crop, like any other manure. About twenty-four bushels per acre are recommended for wheat, and half as much more, or thirty-six bushels, might be beneficially applied for turnips or mangel wurtzel. The most beneficial quantities will easily be ascertained by the intelligent farmer."

Mr. Hall produced a sample of the manure—a coarse black powder, having a strong smell somewhat resembling coal-tar. Samples of the wheat grown by Mr. Daniell were also exhibited, and it was stated, in reply to questions, that the crops produced were greater in quantity, better in quality and weight, and produced with one-third the ordinary quantity of seed. The manure will probably be about one-third the present price of bone dust.

NEW ARTIFICIAL MANURE.

From the same.

The knowledge of the ingredients of the celebrated artificial manure of Mr. Daniell, has at length reached this side of the Atlantic. They are as follows:

Any wood mechanically reduced to powder—in plain words saw-dust—this is the basis, and it is to be thoroughly saturated with bituminous matters of all or any kind—to this is to be added small proportions of soda and quick lime, and a very small quantity of sulphur.

The principles on which this compound is formed appear at first rather obscure, but one thing is apparent, it is an attempt to make an artificial bituminous coal and to keep this in a state of slow combustion with only the substitution of soda for the potash of the wood and the addition of quick lime. We are not told the proportions, nor how long the compost is to remain before used, nor what the bituminous matters are; the only additional information is that it should be buried two or three inches under the surface of the soil.

Before I proceed farther with an analysis by reasoning of this new artificial manure, I must lay before you well authenticated proofs of the value in agriculture of the products of the combustion of bituminous coal.*

Bituminous coal contains from 13 to 16 per cent. of nitrogen or azote, and 4 to 12 per cent. of hydrogen—when the coal is burnt, these two gases unite and form ammonia—when burnt in the open air the ammonia goes partly into the atmosphere and is partly condensed in the soot. When it is burnt in retorts for the purpose of affording gas for illumination, the ammonia is dissolved in the liquor used for purifying the gas, and is called the ammoniacal liquor of gas works. According to Mr. Blake of the Boston gas works, 1 chaldron, or 2700 pounds, gives 33 gallons of this liquor, containing 5 per cent of ammonia, and 24 gallons containing 4 per cent—but the strength of this

* Turner's Chemistry gives the following proportions of nitrogen in 100 parts of coal:

	Caking coal.	splint coal.	cherry coal.	canel coal.
Nitrogen	15.96	6.25	10.22	13.72

There is much reason to suppose that these amounts are considerably overrated.

liquor generally varies in different and also in the same gas works.

In the Gardener's Chronicle, 2d of April, 1842, is a detail of the following experiment made with this liquor :

A large quantity of this ammoniacal liquor was tested for its strength—it was found that it took 5½ pounds sulphuric acid, containing 65 per cent. dry acid, to neutralize 87½ lbs. liquor. It was then divided into four parts—in the first the ammonia was neutralized by phosphoric acid, forming phosphate of ammonia—the second with sulphuric acid, forming sulphate of ammonia—the third with nitric acid, forming nitrate of ammonia—the fourth with muriatic (hydro-chloric acid) forming muriate of ammonia.

Each of these solutions were so mixed with these acids, that the quantity of ammonia in each was the same ; they were much diluted, and half a pint of this dilute solution was given to each plant every other day. Thirteen experiments were made with 25 cabbage plants each. The weight of the cabbages, taken up in the autumn, was as follows :

No. 1. Liquor neutralized by phosphoric acid, to which was added 300 grains of a mixture of sulphate and phosphate of lime. 103 lbs.
No. 2. do. by sulphuric acid and the same mixture, 99 lbs.
No. 3. do. muriatic acid do 73 lbs.
No. 4. do. nitric acid do 65 lbs.
No. 5. do. with carbonate of ammonia dissolved, leaving the same amount of ammonia with the earthy salts, 58 lbs.
No. 6. do. with phosphoric acid but no sulphate or phosphate of lime, 62 lbs.
No. 7. do. sulphuric acid do 39 lbs.
No. 8. do. muriatic acid do 29 lbs.
No. 9. do. nitric acid do 23 lbs.
No. 10. do. carbonate of am. do 12 lbs.
No. 11. do. with dung alone, 37 lbs.
No. 12. do. without dung, 23 lbs.
No. 13. do. Poitevin's dried manure, 40 lbs.

Here No. 5 and No. 10 are useless or perhaps worse,—carbonate of ammonia already existing in the liquor, and the addition of more only rendered the solution perhaps too strong, to the injury of the plants, as the result shows.

In No. 56 of the Scotch Quarterly Journal of Agriculture, is an account of 4 acres grass land put under experimental cultivation,

1 acre with 112 pounds saltpetre,
1 " 168 " nitrate of soda,
1 " 560 " rape dust,
1 " 105 " gal. ammoniacal liquor.

The strength not mentioned, but diluted with five times the quantity of water.

The acre with the nitrate of soda exhibited the earliest luxuriance of vegetation.

That with ammoniacal liquor the next, but this soon surpassed all the rest.

That with rape seed showed the effect the latest, but improved greatly as the season advanced.

The produce from 31 square yards of each was, in weight of grass—

With saltpetre, } nearly the same, averaging 98½ to 100 pounds.
" nitrate of soda, }
" rape dust, }
" ammoniacal liquor, 126 pounds.

When made into hay under equal circumstances, on the 2d of August, the result was—

with saltpetre, 31 pounds,
" nitrate of soda, 32 pounds,
" rape dust, 30 pounds.
" ammoniacal liquor, 46 pounds.

In experiments with other substances as manure, the product with ammoniacal liquor always exceeded considerably the rest.

These appear decisive experiments, as to the great value of the ammoniacal liquor produced by the combustion of bituminous coal. If, therefore, this new manure will give us an artificial bituminous coal, which will of itself enter into slow combustion and furnish vegetables with this ammoniacal product by degrees as wanted, it must be of immense value to agriculture ; and in truth this operation will have to be judged of by observation of its continued effects as much as by those of its immediate action. The value of bituminous soot as a manure has never been doubted ; but like many other manures, it has too often been applied in such large quantities or in such strong solutions, as have rendered it injurious instead of beneficial. The farther consideration of this new manure I will, however, leave until my next letter.

J. E. T.

THE INFLUENCE OF THE ORIGIN OF SEEDS ON THE QUANTITY AND QUALITY OF CROPS.

*By Dr. Bronn, Professor of Rural and Sylvan Economy in the University of Liege.**

[Translated for the Farmers' Register, from the *Journal d'Agriculture, etc., des Pays Bas.*]

Even to the present day, the cultivators of forest trees have not thought of taking advantage of a phenomenon which is presented to us in the cultivation of agricultural plants, and which, although it has never yet been sufficiently explained, is nevertheless well established. This phenomenon is the influence which seed exerts on the quantity and quality of the crop which is produced from it, according to the different nature of the soil and climate from which the seed has been procured. The good results of this influence have appeared after using seed from a cold climate and a tenacious and cold soil, in a warm climate and a dry and light soil ; but they are also equally apparent under circumstances quite the reverse, provided the soil be not too dry and barren, and the seed has had the opportunity of being developed and coming to perfect maturity. It appears then that the two opposite kinds of soils and climates profit equally from a change of seed. Let us consider and examine at first a few observations which may serve to explain this phenomenon, and thence endeavor to deduce the physiological law, and apply it to the cultivation of trees.

The advantages resulting from a change of seed are generally recognized in the cultivation of the

* Professor Bronn's article is here republished, in obedience to the request of one of our most valued correspondents, made in the early part of this volume. It now receives additional value from the remarks appended.—Ed. F. R.

cereal plants. In some mountainous countries, in Scotland for example, they bring the seed from the low country and from the plains, where the climate is more mild, and consequently the seed more forward, a quality which it always preserves for several generations. We are convinced that the cultivator of this mountainous district, if he always used seed from his own crops, would reap later and later harvests, so that at last perhaps they would not come to perfect maturity; a circumstance easily explained by the short duration of summers in the mountains. If, on the other hand, the cultivator of a flat country, the climate of which is mild and the soil dry and light, continually made use of his own seed, it would head every year sooner, the stalks would become shorter, and the heads and grains smaller and smaller, and in time there would result but a poor produce. In this last case the cultivator brings his seed with advantage from a country more cold, the soil of which is good and substantial. Probably these are the circumstances on which rests entirely the difference between the cereal plants of summer, and those of winter, a difference too variable to be easily determined.

The flax, without doubt, presents us with the most striking example of this phenomenon. We, with great advantage to our crops, bring our seed from Riga, *i. e.*, from a colder climate—the sowing of which causes the grain to be slowly formed, and thus leaves more time for developement of the stalk, which is the principal object of its cultivation. To judge by analogy, we would be led to believe that the result would be the same, were we to obtain from a colder country and a colder soil the grain of the clover and other plants used for forage, in the cultivation of which our object is large stalks and a well developed foliage. Even at the present day we are without experience on this head.

Generally, all plants which are principally cultivated for their grain or fruit, need little or no manure; while manure is necessary for those plants from which we wish to obtain large stalks and leaves.*

Fruit trees which shoot vigorously, generally bear little or no fruit; and every circumstance, which on the other hand prevents the too great growth of wood, favors the formation of fruit. On this observation rests the cultivation of dwarf fruit trees, and espaliers; also that of the vine, &c.

Field plants and plants of the kitchen garden (under equal circumstances in other respects) blossom sooner in dry, warm and clear summers, and their stalks as well as leaves are smaller, than in rainy and cloudy summers.

From these and many other analogous observations, we can deduce a physiological law of the greatest importance in the cultivation of plants, to wit: Every thing which favors the disproportioned growth of vegetables, opposes or retards their propagation or formation of fruit; and *vice versa*, the formation of fruit is hastened and forwarded at all times when exterior circumstances prevent the full developement and disproportioned growth of the stalk.

Now to apply this law to the rearing of trees, I ought first to remark that many of the phenomena which I have mentioned, are equally apparent in the vegetation of forest trees, although they have not been so much noticed. In fact we see the greater part of our forest trees bear seeds sooner, more often, and in greater quantities, with a south exposure, and in a dry and light soil, than with a north exposure, and on a cold and stiff soil; while under the latter circumstances they acquire greater dimensions.

Many trees, the birch for example, vary with regard to the time of budding and formation of seed, some being forward, and others late. It is well ascertained that those which bud late, have the hardest, heaviest, and in every respect the best timber, and increase more in volume within a certain time, than the more forward kind. It is not yet proved that the same phenomena may take place relative to age, *i. e.*, that there may be varieties which blossom and bear seeds, and the growth of which consequently diminishes at different ages. This appears very probable, since we frequently see larches, firs, birches, &c., trees which had their origin in a cold and elevated country, bear seeds in a low, dry and warm country, after having scarcely reached the age of ten or fifteen years, and ten or fifteen feet in height; and the growth of which afterwards becomes sensibly slower.

From this observation we may conclude that the trees of cold climates produced from seeds gathered in dry and level countries will degenerate after many years to dwarf trees, shrubs, bushes, &c. which will scarcely ever be of any value as forest trees. Every attentive cultivator of forest trees will have already noticed similar examples, which will justify this conclusion.

From all that precedes, I deduce for the rearing of timber trees this general law: It is necessary to procure, as far as possible, the seeds from a colder climate, and a colder and stiffer soil, than the climate and soil of the country on which you wish to rear these trees.

One of the best things for cultivation in the sandy lands of the provinces of Limburg, of Anvers, and of Northern Brabant, is undoubtedly the sylvan pine, [*pin sylvestre.*] According to the rule just above, the seed gathered in this dry and barren country should not be used, but ought rather be brought from a colder country, or from some place, the soil of which is colder and stiffer. Since some time back, in France and elsewhere, the preference is generally given to the seeds of the pine from Riga, Norway, Scotland, Haguenan, &c., and the rule which it is my wish to establish, has thus been followed by us, but without our having been able to justify this preference by reasonable motives. We have been content to regard the pines of this country as a particular species or variety.

The fir *epicea* (a northern fir,) and larch, are suitable to be reared in the mountainous lands of Ardennes. If we used the seed which grows

* The author's meaning must be taken with reference to the usual rotations of his country, according to which, crops raised for their seeds, are preceded or followed by grass crops, or others, in which the bulk of the whole plant is of far more importance than the quantity or the perfection of the seeds—and according to his theory, crops of the latter kind would receive so much more benefit from the manure than the former, that economy requires the farmer's limited stock of manure should be given to the one kind, and not to the other.—*Ed. Farm. Reg.*

in the dry and sandy parts of Limburg, Anvers, and Northern Brabant, we would raise nothing but dwarf trees, which at the age of twenty or thirty years, perhaps, would be covered with mosses, and the growth of which would after that become more slow, and would soon afterwards decay. It is our interest then to bring these seeds from still colder climates and better soils, and from countries in which these two trees grow larger, viz.: from the Alps, Switzerland, the Tyrol, the mountains of Hartz, the Black Forest, and Norway.

The rule which I wish to establish will perhaps become very useful in introducing into this country foreign forest trees, for it is very probable that the little success with which we have met in this important part of the cultivation of forest trees is occasioned principally by choosing unsuitable countries from which to bring the seed.

[The foregoing communication well deserves the attention of all thinking farmers. If Professor Bronn's opinion is correct, we may make it operate beneficially on the practice of every farm, either for the correction of common errors, or the introduction of positive improvements, or for both. Very many cases of the proper application of this theory will readily occur, of which I will mention a few only as examples.

We frequently change our seed wheat, either from choice or necessity, and obtain new supplies from other, and perhaps very different soils—and we decide on the comparative productiveness of any two kinds, most generally, by their growth, as they stand in the field. Yet, according to the foregoing theory, the greater length and bulk of straw may be expected from seed that will yield a deficient crop of grain. By attending to the rule offered, we may make profitable selections of seeds from every single field, by taking from the warm and light soil, if we want the best product of grain, or the cold and backward, if the crop is of a kind to be most profitable in proportion to its whole bulk. Another necessary deduction is, that the farmers of lower Virginia ought often to procure new seeds of clover and other grasses from the mountains, or the northern states, to renew the original bulk and value of those crops, and to prevent their becoming more productive in seed than in hay. And the reverse operation will be equally beneficial as to wheat and other grains, of which the mountain and northern farmers ought frequently to obtain a new stock of seed from the plains and from the south. But even if such considerable changes are not attempted, a less degree of benefit may be obtained by attending to these rules within the limits of almost every farm.

A striking proof of the truth of Professor Bronn's opinion of the influence of climate on seeds is presented in the different times of maturing of the timothy grass of America and the cat-tail grass of England. These grasses are in appearance, and in every respect, precisely the same, except that the English grass is about two weeks later in maturing than the American, when both have been sown together on the same soil, Mr. Strickland made the trial, and states the result in his observations on the agriculture of the United States, reported to the British Board of Agriculture. This difference, which was so fixed, and appeared so remarkable to the observers, is completely explained by Professor Bronn's theory, applied to the temperate and moist summers of England, and the more heated air and drier soil of the United States.—Ed. F. R.]

REMARKS.

Professor Bronn's theory on the influence of seeds is, in the main, confirmed by many facts which have come under the observation of the writer of these remarks. Seeds or trees transplanted from northern to southern soils, mature their fruits earlier than the same species not so transplanted; and *vice versa*.

The northern summer is of short duration, and the progress of vegetation is consequently very rapid. Plants in such climates thus acquire the *habit* of quick growth and early maturity; and this habit is perpetuated for several generations in annual plants, and for one generation at least in perennial plants, upon removal to a southern climate. On the contrary, southern plants, having a long period in which to perfect themselves, acquire a slow growth; and this constitutional tendency is manifested in their offspring, when removed to a northern climate.

In the case of fruit trees, the varieties of the winter apple, introduced into Virginia from the northern nurseries, perfect their fruit early in autumn. It falls from the tree before the usual period of gathering, and is therefore of no value for winter use. The summer apples from the north come early into bearing here, and possess desirable qualities.

Nearly all our best varieties of peaches have originated north of us, or been introduced thence from foreign countries. The latest of any merit is the well known Heath, which ripens here about the 15th of September; in Baltimore from the 25th to the last of September; and in New York so late as seldom to develope its superior excellence. Our earliest peaches are also obtained from the north; for we have no native variety that ripens early in the season. The advantages of our climate are such, that we might have the peach in perfection from the middle of July to the middle or end of October; but as long as we depend upon northern sources for this fruit, we can never have any variety materially later than the Heath. Had the system of originating fruits been practised here and south of us to the same extent as elsewhere, it would have been practicable, by making judicious selections from various sources, to have the peach in regular succession, and in a high degree of perfection, for at least three months.

The northern corn, when cultivated in our climate, cannot be relied on to make a crop. The very early varieties, which produce soft corn for the table in July, may be planted for that special purpose with evident advantage. But for agricultural purposes, no variety of northern corn can produce an abundant yield in this climate. The hardening of the grain takes place in the month of August, the most critical period in the whole season. Those who attempted the cultivation of the famous Dutton corn, a few years ago, may recollect how utterly it perished during the heats of summer.

The northern wheat might be introduced here to great advantage. The influence of the seed extends through two or three generations, and the maturity of the crop is hastened by at least several days. Wheat usually ripens by or soon after the accession of hot weather, so that the effect of a change of seed is more beneficial than in the case of corn. While it is desirable to accelerate the ripening of the one, it is far from being so with the other. September is the proper season here for corn to mature.

All *early* vegetables are grown with decided advantage from northern seed. Gardeners who would have the earliest peas, beans, squashes, and other spring or early summer vegetables, do well occasionally to renew their seeds from reliable sources. But by exercising the greatest care in saving the earliest perfected seeds from their own grounds, most varieties may be preserved in their purity for a length of time.

The writer of these remarks has frequently exchanged seeds, both of useful and ornamental plants, with his correspondents at the north, and occasionally with those at the south. He has also received plants from various parts of the country. The facts above stated are derived from actual experience, and they are submitted as a practical illustration of the physiological principles asserted by Professor Bronn. P.

SOWING CORN FOR FODDER.

From the New Genesee Farmer.

Mr. Colman—In the Farmer for March, your correspondent, Ledyard, asks information on the subject of sowing corn, broadcast, for winter fodder. I was, at first, surprised at the inquiry, but on reflection, concluded he must have been a stranger to your paper, probably just then commencing an acquaintance with it. I ask leave, therefore, to refer him to your number for July, 1841, page 109. He will there find an article on the subject, that will, I think, in a measure satisfy his inquiries. I have been for twenty years accustomed to this culture, and have there given the result of my experience. I do not feel as if I could say too much in its favor. The product per acre, on a rich soil, and in a favorable season, will be very great. I have never had occasion to ascertain with accuracy the amount. But have considered, or estimated the amount, on different fields and in different seasons, to vary from five to seven tons, or more per acre. I have carried well a very large stock, rising 1000 sheep, and many cattle, far into January, with very little hay.

I would by no means suffer the corn to stand to let the ears ripen before harvesting. It should be cut when most juicy, when the juice is richest and sweetest. This will be, I suppose, at the time when the kernel has become nearly or quite full of milk. When sown 2½ bushels of seed per acre, the quantity which I recommend, and from which I would not vary, it will stand so thick and the stalks be so slender, that but few ears will set. Cut up at the time I propose, it will be so extremely succulent, that it will need to stand in small stouts to cure, during the dry and hot weather; and should be put into stacks, as recommended in the article referred to above, just before the fall rains commence.

The idea suggested in the Farmer for March, page 34, "that weeds will check its growth, if the land is rich, and fill the ground with seeds," I cannot think correct. It is entirely at variance with my experience. The ground is so deeply and perfectly shaded, that I have found nothing could live or grow among it, save the Canada thistle; and this would shoot up a slender, pale, weak, and sickly stalk, unable to produce or sustain a blossom.

I have been pleased, after taking off the corn, with the condition of the ground for cross-ploughing and sowing with wheat. I recommend to sow corn early, that it may be harvested early, and thus have the full benefit of the dry and hot weather, for the process of curing the stalk. If cut late, it will be more difficult so to cure it as to secure its safety. I once lost a large quantity, supposed well cured, by stowing it away in a large and solid mow. Of course, I prefer stacking it, as recommended in the article referred to above, around a pole, the length of a sheaf only from the pole, so that the butts shall all be exposed to the air. A FARMER.

April, 1842.

SLUGS DESTROYING THE COTTON CROPS.

A new enemy to the cotton planter has made its appearance in Panola and De Soto counties, Miss., in the shape of innumerable snails, which eat up and destroy the plant, commencing with the leaf and ending their repast with the bud. They are apparently the common-sized snail without a shell, such as may be found adhering to the bark of trees in wet weather. Several entire cotton plantations have been ruined by them.—*Compiler.*

This new and most destructive ravager, the naked snail, or *slug*, may be effectually and cheaply checked by sowing a few bushels of quick-lime to the acre, on the fields infested. See an article copied from an English journal, giving full directions, at page 216, vol. ix. Farmers' Register. This is one of the many cases, in which a little book knowledge, as much despised and disregarded as is such knowledge by farmers' and especially by cotton planters, might save hundreds or thousands of dollars to individuals, and millions to the country at large.—ED. FAR. REG.

THE FRUIT GARDEN.

By David Thomas, of Cayuga county, N. Y.

From the Transactions of the New York State Agricultural Society.

In traversing our wide spreading county, the pomologist must observe with regret that so few of the landed proprietors enjoy the luxuries of the fruit garden. The stately mansion, the comfortable farm-house, or the neat cottage, may meet his view in every direction; and well cultivated fields, loaded orchards, and abundant harvests, indicate that plenty reigns within; but if he stop and inquire for the finer fruits of the garden, what answer would he get? In nine cases out of ten, perhaps, their names would sound like the words of an unknown tongue; and the lord of the soil know as little about them as he does of the *lotus* of Lybia, or the *mangosteen* of India.

How many of our freeholders have ever tasted an *apricot*? How many of them cultivate the best *cherries*? How many know that delicious *plums*, always fresh from the tree, may be had from early wheat harvest till the ground freezes in autumn? How many eat the finest varieties of the *peach*? How many think of having "the circle of *pears*?

These questions if duly examined and considered, would show our deficiency—for deficiency, omission, or neglect it must be, not to provide for all the reasonable wants of our families. Now fine fruit in abundance would supply a reasonable want. The relish for it is prevalent throughout every class of our population—from the honored guest who regales on what is set before him, down to the school-boy who stops to plunder by the way.

Hundreds, however, may think, or say, "We have no time to attend to such trifling affairs." This plea might be allowed while a man was struggling to save his property from execution, or his land from the foreclosure of a mortgage: but from him who basks in prosperity, it would come with an ill grace. Every day comforts are not *trifles*. Luxuries which delight the palate, and conduce to health, are not *trifles*, yet well ripened fruits belong to this class; and we are satisfied that much suffering, and many a doctor's bill, might be saved by a plentiful supply.

It may be said indeed, that fruit often causes illness. So grain often causes founder; and cold water often causes death; but it is the *excess* that proves baneful or destructive. Half-ripe, crude, unwholesome fruits have no attraction for him that has free access to the fruit garden: it is the unfortunate wight for whom nobody has planted or provided, that incidentally suffers.

One hundred trees in most cases, would furnish an ample supply for a family, and may be selected in the following proportions:

15	cherry trees,	at 37½ to 50 cents.
8	apricot do.	37½
25	pear do.	37½
15	plum do.	37½ to 50
20	peach do.	25
5	nectarine do.	25
8	quince do.	25
4	early apple do.	25

The common nursery prices are added; and the annual interest on this sum, whether *borrowed* or *appropriated*, would barely replenish a tobacco box through the year.

Now a fruit garden containing this number of trees, ought to yield a constant supply of *cherries* for two months; of *apricots* for one month; of *pears* for nine months; of *plums* for three months; and of *peaches* for two months.

One hundred trees would do well on *half an acre;* but if we allow a square rod for each tree, the fruit garden would only be ten rods square. Now a lot of this size may be conveniently appropriated on every farm; and where is the owner who cannot build forty rods of fence? Let him listen, however; thorny shrubs would afford the best protection—not against quadrupeds, but Plato's "two legged featherless animals;" and the sooner such a hedge is planted the better.

Unfortunately for the moral character of our population, fruit is too generally considered lawful plunder. The culturist is allowed to have a full and exclusive right to his corn and potatoes—it would be infamy to steal them; but no exclusive right to his fruit—if they can get it. Thousands of honorable exceptions to this charge, indeed, may be found, but it is not the less true that a great part of our population is tainted, and deserves to be branded with reproach.

The native fruit of a thinly populated country, growing without culture, and free for all—has doubtless had its share in producing this laxity of morals. "I would sooner have a hundred Irishmen around me than one Yankee," was the declaration of a sufferer, whose fruit had been plundered near the lime of the Erie canal, when that great work was in progress. But Europeans are generally more exemplary on this point than Americans—shame on us! When Professor Stowe was in Prussia, where the roads are lined with fruit trees by order of the government, he observed a wisp of straw, attached to particular trees, to protect the fruit: a sufficient guard; but he suggested to the coachman that in America, it might only prove an invitation to plunder. "Have you no schools?" was the significant reply.

Yes, we have schools; but how many where the child is taught to respect his neighbor's property? Too often he acquires literature and vice at the same time. The State of New-York is famous for her schools and her prisons; the latter to supply the defects of the former system, which they do, however, very imperfectly. Better let the mandate go forth that the *morality of the Bible* shall be *one* of the chief objects of instruction. *Teach her children to be honest*, and then with science and literature, a foundation for true greatness and prosperity would be laid.

One thing is worth bearing in mind by those who purchase fruit trees: the *best kinds* are generally as *hardy as the worst*, and the difference in price fades into nothing when compared with the difference in *quality*. Nobody is satisfied with mean fruit after tasting better.

For a fruit garden, a western aspect is generally best, because it is the least subject to sudden transitions of temperature. Severe vernal frosts often prove injurious, or otherwise, according to the weather that follows. If the sky be overcast in the morning, and the air continues cold, little or

no damage occurs; but when the sun breaks out warm, the injury is greatest; and the most so, where the trees are most exposed to his rays. For this reason, a hill or a wood on the east side, may prove very beneficial.

A northern aspect would go far towards insuring regular crops of the peach, nectarine, apricot, if protected from the sun and warm winds by a belt of evergreens. On sandy soils especially, the reflected heat is often sufficient, in autumn or winter, to *start* the buds; and snow and ice have been successfully* heaped round the trees to prevent this disaster; but a northern aspect would probably render such labor unnecessary.

Dry firm ground should be chosen, preferring a sandy or gravelly loam, though clay will do with good culture. Wet, peaty, or spongy soils are apt to be frosty; for the radiation of heat is much greater than from firmer land.

Four *orders* of arranging or planting trees have been employed, which the annexed figures exhibit, all drawn by the same scale; and the distance between the nearest points (or trees) is intended for one rod. One hundred of these are represented in two of the figures; but in the *quincunx*, owing to the vacancies in the sides, only ninety-eight are given, while in fig. 3 there is a surplus, although some vacancies also occur at the sides.

The *first order* requires less calculation, and is more generally in use than any other; but in laying out the ground, the boundaries should be first accurately determined; and the lines may then be drawn across it with precision. No less care and attention in this respect, however, would be required by the other *orders*.

The *quincunx* fig. 2, is only a series of squares laid off diagonally; and we cannot perceive any advantage that it has over the common square, though it was formerly much in fashion.*

In the *third order*, each tree (except at the sides) is surrounded by six others, all at equal

* We caused an apple tree to bloom a fortnight later than the rest of the orchard, by piling wood round it.

* Pope said of Lord Peterborough,

"Even he whose lightnings pierced the Iberian lines,
Now forms my QUINCUNX, and now ranks my vines."

distances—in other words it stands in the centre of a *hexagon* made of six equilateral triangles. The trees are thus more equally distributed over the ground than by any other arrangement; and if cultivated by the plough, the furrows may be drawn in three different directions.

The *fourth order*, as explained by the figure, may be considered as rather a new proposition; but where a team is to cultivate the garden, the plan has some decided advantages. The spaces between the rows, are wide enough for the deepest ploughing, though it should be more shallow near the trees, and in no case come close enough to touch them. A lighter plough with one horse walking in the last furrow, however, may continue the work, and save much manual labor. And where nutriment is so near, the roots will soon find it.

To lay out the garden according to this plan draw the line for the first row, one rod from the fence; then leave a space two rods wide, and draw another line; and so on till the fifth row be completed, which will be one rod from the fence on the opposite side. This distance will allow room enough to plough between the trees and the fence, and for them not to hang over and tempt prowlers to reach the fruit on tiptoe.

Now 10 rods are 165 feet, and 32 substracted leave 133 feet, the distance between the first and last trees in the row. For 20 trees, 19 intervening spaces are wanted; and 19 into 133 give seven feet for each space. The trees though crowded *lengthwise*, will find ample room to spread *laterally;* and our experience is decidedly in favor of this method.

It has been found very useful to keep swine and poultry in the fruit garden, on account of their services in destroying insects, and especially the curculio. In many instances no other protection has been necessary; but where the garden is large, the *plum*, *apricot*, and *nectarine* should be planted in the same *quarter*, so that the hogs, if wanted, may be confined amongst them for a time. *Cherries*, and even *peaches*, would also receive benefit from their presence, though these fruits generally suffer less from this insect than the former sorts. Cherry trees, however, should stand near together, so that from a central seat, a load of shot may protect them. We do not mean that all birds fond of cherries should be destroyed, but only such as take more than a reasonable share, or that render no services in return.

Many people have a prejudice in favor of birds that no well balanced mind should entertain. "Denizens of the air," have no more right to our property than denizens of the earth. Plunderers on two legs are not more respectable than plunderers on four legs; and cedar birds are entitled to no more regard than rats, unless personal beauty can atone for moral deformity.

Ornithologists often become partial to the subjects of their study, and side with them against the farmer and the gardener—magnifying their services and overlooking their trespasses. The laborer, indeed, may drive the geese from his cabbages, throw stones at the crows, and even shoot a hawk—but not the birds that devour his cherries?

An amiable writer, in reference to such visiters, says, "Such has been the security they have felt in our grounds, and so great their increase, that not only *cherries*, *gooseberries*, and *currants*, but *apples*, *pears*, and *plums*, have been ravaged; and it may become a matter for serious consideration whether in continuing our protection, we do not risk the *total loss* of some of the most desirable appendages to the dessert." Now if called into council, our advice would be prompt and brief: Treat them according to their doings. Make pies of the robins, orioles, and cedar birds—one chicken is worth a dozen of them for business; but save and protect the blue birds, warblers, and sparrows—these are always our friends.

Stunted trees always produce smaller fruit than when the same kind grows on vigorous branches; but the fruit suffers in *flavor* as well as in *size*. The trees should therefore be planted in deep beds of fertile soil. In dry seasons, more especially, this provision is of great importance; and young trees treated in this manner are not only more likely to live, but grow much faster, bear much sooner, and bear much better fruit than on sterile land. All our observations go to justify these remarks.

When young trees are taken from the nursery, inquiry is often made how soon they will come into bearing? It is a very proper question, and it would be a proper answer to say: Very much according to the treatment they shall get. When they are set in holes cut out of a sod, just large enough to receive the roots with some crowding, and are then left to take care of themselves, we have no right to expect them to come soon into bearing nor to bear much when they do. Neither half starved cows, nor half starved trees will be found profitable. In the latter case especially, the interest on the purchase money is generally lost for some years, and not unfrequently the purchase too; but we hardly ever lose a tree in good condition, set in mellow ground which is kept mellow.

The holes for the trees should be not less than four feet diameter and fifteen inches deep, but a greater breadth and depth is desirable. Place the soil round the brink of the hole, ready for filling in again; but scatter the harder subsoil back out of the way. The hole should then be filled with the best earth, and rise a few inches above the general surface on account of its settling, first mixing three or four shovelfuls of chip-dirt with the part that is to come in immediate contact with the roots. It helps to keep the ground loose and moist, besides yielding much nutriment to the trees.

The roots of the trees when taken from the nursery should be carefully guarded against *drying* or *freezing*. If such care, however, has not been taken, bury the *frozen* roots in the *ground* before they can thaw, and plunge the *dried* roots with several feet of the main stem into *water*, to soak there from 12 to 24 hours, till the moisture is sufficiently restored.

In planting, spread out the roots carefully, and let the best point against the strongest winds. Fine or mellow earth should fill up all the spaces between the roots, so that every fibre shall come in contact with it on every side; and in order to accomplish this intention more perfectly, throw in a pailful of water when the roots are covered, to wash the earth down, and to fill up every interstice.*

* An experienced horticulturist says, nine-tenths

Newly planted trees being acted on as levers by the wind, often press the earth round their stems aside, and make an opening down to their roots, which in consequence suffer from both drought and disturbance. To prevent this disaster, it is therefore important that stakes should be provided to support and stiffen them. If driven before the trees are planted, they may be erect; if driven afterwards, they may be slanting; and in both cases, straw bands should be first wrapped once round to prevent the trees from chafing.

When trees are set in clay which holds water like a tub, they *soak* and often perish; especially if transplanted in autumn. This evil may be readily prevented, however, when the plough can be introduced, by drawing several very deep furrows where the trees are to stand, clearing out the loose earth with the shovel, and then employing chips, brush, potato tops, straw cornstalks, or old rails, in constructing an under drain. Even if made with these materials, it would last for an age, for when mouldered into earth, the water would soak away along the seam.

Early in summer, after the trees are planted, let the ground be well dug round with the spade, commencing shallow near the trees, but deepening as soon as there is no danger of disturbing the roots. One spading is worth several hoeings, though the broad hoe may be profitably employed once a month after the spade has thoroughly loosened the soil. Trees managed in this way, will grow much faster than if the ground were just scratched over to the depth of an inch or so; and many of ours have grown as luxuriantly through the late excessive drought, as if they were in want of nothing.

The pruning of young trees to prevent their *splitting down*, is a very important operation. Many are greatly injured, and sometimes ruined, for want of this precaution. Where the limbs diverge considerably, nature has provided a kind of net-work of the firmest wood to connect them together; but where two leading branches take nearly the same direction, they soon begin to press against each other; and the bark interposing, the wood is prevented from uniting. The consequence generally is, that when loaded with fruit, they are broken down by the wind. Now it is far better to cut off the limb in time. No material loss is sustained, as all the nutriment flows into the other branches, and increases their vigor.

The advantage of pruning apple trees, is generally known; and unless many of the limbs are cut out, some of the finest varieties become comparatively diminutive and insipid. The same care, however, is rarely extended to other fruit trees. When the twigs become stunted and mossy, sometimes they are trimmed by the tempest, or broken down by an untimately fall of snow; and then the benefits of pruning are manifest, even when done in that rough style. It is better, however, to depend on art than accident. As a general rule the best flavored fruit of the kind grows on the most vigorous branches well exposed to the sun and air; and with this idea constantly before us, we shall hardly do amiss when we apply the axe, the saw, or the chisel; though we may specify that cross branches should be lopped, and thrifty shoots that have room to spread, should be saved.

The tree mosses are parasitic plants, and should be expelled from the fruit garden. Lye is often used for this purpose on the apple tree; but we think it is no better than lime whitewash, which purifies the bark, and leaves it in a fine healthy condition. Once a year is quite sufficient.

Under deep snows, or snow drifts that settle round the trees, the *meadow mouse* often gnaws the bark to their great injury or destruction. This animal however always *works under cover;* and therefore the damage may be generally prevented by piling mellow earth round the stems, a foot high, late in autumn. The snow as it falls, is generally swept away from the pile by the wind; and even if the mouse should persist in climbing up on the earth—which we have not known him to do—he would soon come out into the open air, except when the snow was very deep.

Another method which has never failed with us, though requiring attention—is to *tread the snow firmly down round the stems;* and this should be carefully done every time that a deep snow falls, or whenever a drift is forming round the trees. The mouse, as he roots along, always turns away from the hardened snow.

Trees completely *girdled* by the mice, however, may be saved by setting grafts *early* in the spring to restore the communication between the two detached portions of the tree—in other words, by grafting them together. Part of a small branch should be *inlaid*, both above and below; and if skilfully done and carefully coated over with grafting mud or wax, it will be very likely to grow, except on the peach or nectarine. We have succeeded in this way on a pear tree; but three or four should be set round the tree.

Cultivated *cherries* belong to several species, which have spread into many varieties, and probably *hybrids*. The caterpillar sometimes feeds on the leaves; and the curculio punctures some of the fruit which in consequence becomes *wormy;* but no fruit tree yields a more certain crop, bearing every year without intermission, unless the blossoms or young fruit be damaged by frost. Some kinds, however, as the *morello*, have been nearly destroyed in some parts of the country by the "*black gum.*" This excrescence is caused by an insect which should be carefully sought for, late in the spring or early in the summer; and as soon as the bunches appear, the limb should be cut off and burnt.

The *slug*, another insect, feeds on the pulpy part of the leaf, despoiling its verdure and wasting the vigor of the tree. It might almost be mistaken for the filth of some little bird. It soon renders itself conspicuous, however, by its works; and though it sometimes attacks the foliage of other trees, the cherry leaf appears to be its favorite food. It may be destroyed by throwing fresh ashes among the branches by means of a shingle—every worm that is covered perishes. It has been done when the dew was on the leaves; but if the slug is moist enough of itself to catch the ashes, it would be better to apply them when the leaves are dry, because the latter would neither be injured by the potash, nor defiled by the dust.

The cherry tree is more impatient of *nuisances*

---

of the deaths from transplanting arise from the hollows left among the roots of trees by a careless and rapid mode of shovelling the earth in about the roots.

than most other kinds. Some have been destroyed by ashes thrown round the stem. Under two trees, the pigs were fed with corn, and the cobs scattered over the ground: both perished. In a slight depression near another, the water collected in rainy weather, and the geese dabbled in it: the tree died the same summer. Lime whitewash has also been charged with injuring the cherry tree; and if it be used at all, the experiment should be cautiously conducted.

The *morello* and *Kentish* appear to be adapted to a greater variety of soils than the *heart* cherry trees; and may be employed as stocks for the latter in unfavorable situations. The outgrowing of the stock by the graft, constitutes no valid objection. We have never seen a tree endangered by such overgrowth, while the obstruction to the descent of the juices, favors the enlargement of the fruit.

The *apricot* was formerly ranked with the plum, but it differs enough to stand separate. Like the plum however, it has a smooth stone, and turns sour with heat; though in flavor it resembles the peach more than any of our fruits. It resembles it also in the excitability of the fruit buds in winter. Its earlier bloom exposes it rather more to severe weather in the spring, but generally it succeeds wherever the peach can be successfully cultivated. In this climate, the tree is perfectly hardy.

There are two species of the apricot: the black, and the common sort, which has spread into many varieties. Ripening earlier than the peach, their presence in the fruit garden is very desirable.

Neither the borer nor the caterpillar attack the *pear* tree; but sometimes flies, wasps, and hornets are busy among the leaves, showing that all is not right, and that honey dew emitted by plant lice, attracts them. But this tree is subject to a more serious injury, to wit: the *fire blight*, which occurs early in summer, the leaves from the extremity of the branches for two or more feet, appearing as if they were *scorched*. We think however, that two distinct causes occasionally operate to produce similar effects, namely: insects, and a starting of the bark in winter.

The late Professor Peck on examining the branch of a pear tree which had died with fire blight, said the damage was caused by an insect (*Scolytus pyri*,) and that to cut off the limbs a foot or more below the dead part, and *immediately burn them*, would be the proper remedy. We have faithfully followed this advice; and though the fire blight has been several times in the fruit garden, its ravages have always been arrested at once, so that we have not lost a tree from this cause in twenty years. We have believed that the new colonies went with us when we carried off and destroyed the branches.

The starting of the bark in winter, appears to be caused by an untimely flowing of the sap, followed by intense cold, which expands it into ice, and separates the bark from the wood. We have observed such effects once or twice, succeeded on some of the smaller branches by a blighting of the leaves, but we believe it seldom occurs in this district.
